Less than half (40%) of early childhood wheezers have persistent wheezing from 3 to 6 years of age, and about half of them become sensitized to inhaled allergens before school age. These sensitized persistent wheezers are called atopic wheezers. The first wheezing episode usually takes place during the second or third year of life, and is later followed by repeated wheezing episodes, allergic sensitization and subnormal lung function, continuing through the whole childhood. In contrast, persistent wheezers with no allergic sensitization usually start wheezing before 1 year of age, typically induced by RSV infection. They subsequently wheeze only during respiratory infections, with a decreasing tendency by age. At the age of 13 years, the risk for wheezing is only slightly greater than in control children. Whereas, lung function remains subnormal through the childhood—also in nonsymptomatic cases.

WHEEZING AND ASTHMA

Children with wheezing severe enough to need hospital treatment at less than 24 months of age form a group at a particular risk for asthma and other respiratory disorders in later life. There are only four prospective follow-up studies after hospitalization for bronchiolitis, which have continued until more than 10 years of age (Fig. 1). Over half of the former bronchiolitis patients have suffered from recurrent wheezing episodes at 2 to 3 years of age, and 25 to 54 percent have been symptomatic at 4 to 6 years of age. Although the tendency for wheezing decreases over time, still 15 to 30 percent have asthma during the early school years.

Many cohort studies have suggested that children with wheezing symptoms, or even with asthma, outgrow their disease by the second decade of life. The experience from clinical practice is similar, as are also the recent

Table 1: Three phenotypes of early childhood wheezing

	Age (years)

research-based observations on the phenotypes of childhood wheezing. Over half of the wheezing children have transient wheezing and become symptom free before 6 years of age. In addition, nonatopic children with wheezing persisting until 6 or more years of age become symptom-free by 11 to 13 years of age. Studies have revealed that many former wheezers become symptomatic again in adulthood, often after many symptom-free years. Relapsing symptoms seem to be particularly typical for children with severe bronchiolitis and pneumonia needing hospitalization.

As seen in Figure 1, 14 to 40 percent of former bronchiolitis patients had asthma in adolescence and/or at teenage. The prevalence of modest to severe asthma at 17 to 20 years of age was 16 to 30 percent, and the prevalence of all asthma cases was 41 to 43 percent. The figures are

1.5 to 3.0 fold when compared with the figures at 7 to 10 years of age in the same cohorts and about 5-fold when compared with age specific population data. When the studies are compared, a clear secular trend is to be seen.

LUNG FUNCTION

Longitudinal studies have revealed permanent loss of lung function after bronchiolitis. Later lung function abnormalities have been documented after severe bronchiolitis in infancy and after mild early-life wheezing, and even years after cessation of wheezing. It is observed that adulthood lung function remains persistently impaired in subjects with childhood asthma, when compared with healthy controls. Instead, children with periodic wheezing with no asthma tend to have normal lung function until 40 years of age, but thereafter show a rapid decline. In atopic wheezers, lung function deteriorates with time and with continuing symptoms. In nonatopic transient and persistent wheezers, lung function gradually improves, but on average, remain subnormal through childhood—even after 5 to 10 symptom-free years. All these observations speak for the presence of a subgroup of children who are prone to permanent airway damage caused by early viral infections, along with other environmental factors such as early passive smoking. In later life, they are at risk for other respiratory disorders, like rapid deterioration of lung function from the age of 40 years onwards.

Viral Associated Wheeze

Viral respiratory tract infections are the most important trigger of asthma in children. Recurrent wheezing and asthma are common for some years after hospitalization for RSV bronchiolitis, but then decrease at preschool and school age with continuing tendency until early adolescence. Similar trends have been observed after hospitalization for pneumonia caused by RSV. It is observed that children with mild RSV bronchiolitis or other RSV infection treated at home before 3 years of age had a 3 to 5-fold risk of wheezing at 6 years of age, but the risk was no longer increased at the age of 11 to 13 years. However, their lung function still was lower than in controls.

Studies reveal hospitalization for RSV bronchiolitis at less than 12 months of age was a significant risk factor for both asthma and atopy at 7 to 8 and 13 to 14 years of age. The long-term follow-ups of these children have stressed the role of bronchiolitis not caused by RSV, or caused by rhinoviruses, as a risk factor for later asthma.

Other picornaviruses like enteroviruses, and parainfluenza viruses, human metapneumovirus and the newly found bocavirus have recently been established as triggers for wheezing in early life. In two recent studies, metapneumovirus bronchiolitis had similar presentation and outcome as had RSV bronchiolitis, but follow-up data have thus far been available only until 5 years of age.

The role of viruses in the development of asthma may be causal which means that viral infection in early life alters the normal lung development. On the other hand, viruses may act as triggering factors and reveal those infants who have a pre-existing aberration of either airway function or immune system. Probably, the association between viral infection and asthma is more complex, consisting of genetic constitution, concomitant exposure to multiple environmental factors and the maturation of the infants' airways and immune system at the time of infection.

Risk Factors

Parental asthma, parental atopy, elevated total serum IgE, early sensitization to inhaled allergens assessed either by allergen-specific IgE in serum or positive skin prick tests and blood eosinophilia have been predictive for asthma at teenage and also in young adults.

Table 2 summarizes early predictors for teenage or adult asthma. Asthma in parents, atopic asthma in particular, was a major predictor for wheezing and/or asthma at teenage and in adulthood, stressing the role of inheritance in the development of asthma. In a recent study, the authors identified a link from atopy in family members to the development of atopy and further to the development of adulthood asthma after early childhood wheezing. Since early childhood wheezing is more common in

boys than in girls, the female gender seems to be an independent risk factor for later asthma.

Early exposure to inhalant allergens may lead, depending on the timing and quantity of exposure and on inherited properties, to sensitization with increased risk for allergy and asthma or to tolerance with decreased risk. Thus, population-based studies on early exposure to furred pets have given varying results, from increased asthma risk in children with asthma in parents to decreased asthma risk, at least until 13 years of age, in children with no asthma in parents.

Eosinophils are involved in the inflammatory process of airway obstruction, at least in adults with asthma, and have been suggested to contribute to the development of subsequent symptoms and later asthma in wheezing children. Lack of eosinopenic response to acute viral infection, elevated blood eosinophils in infancy during acute bronchiolitis, and persistently high blood eosinophil counts at control visits have predicted wheezing and asthma until school age.

Wheezing induced by other viruses than RSV, and recurrent wheezing episodes before the age of 24 months, are significant predictors of later asthma, and the influence is to be seen until adulthood.

Maternal smoking, particularly if present during pregnancy, seems to increase the risk for later wheezing during childhood. Although the harmful effects seem to decrease with time, there is increasing retrospective evidence of permanent damage to the airways, manifesting as reduced lung function, increased risk for asthma or wheezing symptoms continuing until adulthood. The effect is intensified by later active smoking. The influence of paternal smoking is less evident, but a significant association with active smoking later and an increased prevalence of asthma until adulthood has been observed.

There is increasing evidence that an early exposure to tobacco smoke leads to increased airway reactivity and further to adult asthma. Such an early exposure leads to subnormal lung function in adulthood. The harmful effects are mediated by nonreversible changes in the airways, persistence or development of bronchial hyper-responsiveness and increased active smoking in young adulthood.

Distinguishing which bronchiolitis patients are at a particular risk for persistent wheezing and asthma in later life is essential for planning of an optimal treatment for early life wheezers. This means avoiding both under-treatment with a risk of complications, like permanent impairment of lung function, and over-treatment with potentially harmful medicines like steroids. Therefore, algorithms based mainly on the recurrence of wheezing and clinical manifestations of atopy in children, and asthma in parents, have been constructed for clinical use. However, waiting for the recurrence of symptoms may delay the treatment, and not all atopics present with clinically evident symptoms in early childhood.

Table 2: Early childhood factors associated with the development of teenage or adult asthma: postbronchiolitis studies

<i>Factor</i>	<i>Author</i>
Inheritance

Parental smoking	Goksör 2006

Table 3: Algorithm to define those wheezing children who are at particular risk for subsequent asthma

<i>Major criteria</i>	<i>Minor criteria</i>
1. Physician-diagnosed asthma in a parent	1. Physician-diagnosed allergic rhinitis*
2. Physician-diagnosed atopic dermatitis	2. Wheezing apart from colds
	3. Blood eosinophilia ($\geq 4\%$)

*Sensitization to inhaled allergens.

Table 4: Revised algorithm to define those children who are at particular risk for subsequent asthma after hospitalization for early childhood wheezing

<i>Major criteria</i>	<i>Minor criteria</i>
1. Physician-diagnosed asthma in a parent	1. Sensitization to inhaled allergens*
2. Parental, especially maternal smoking	2. Wheezing induced by other viruses than RSV
3. Physician-diagnosed atopic dermatitis and/or food allergy	3. Blood eosinophilia or lack of eosinopenic response during viral infection

*Either positive skin prick tests or serum allergen-specific IgE.

An algorithm based on a large prospective birth cohort study including wheezing children, mainly treated at home, below 3 years of age has been developed (Table 3). Wheezing at <3 years of age and at least one major criterion or two minor criteria—means moderate risk for later asthma. Repeated wheezing at <3 years of age and at least one major criterion or two minor criteria—means high risk for later asthma.

Studies stress the roles of early wheezing not induced by RSV infection, early atopy and early recurrence of wheezing as risk factors for adult asthma. All these factors were associated with asthma in parents. Early exposure to tobacco smoke, maternal smoking in particular, was associated with lung function abnormalities persisting until adulthood.

Based on these studies algorithms have been revised to be more suitable for infants and toddlers treated and examined for wheezing in hospital (Table 4). There is stress on significant predictive role of asthma in parents and atopy in children as major risk factors for later asthma. In addition to atopic dermatitis, food allergy, at least when presenting with rash or respiratory symptoms, might be included in the model. Likewise, there is a role of early childhood eosinophilia, or merely the lack of normal eosinopenic response to infection, as a risk factor for adult asthma.

However, the recent observations question the roles of allergic rhinitis and wheezing apart from viral infection even as minor criteria in young children. Allergic rhinitis is rare in young children, and moreover, difficult to separate from viral rhinitis, or from rhinitis with involvement with both allergens and viruses. Moreover, new sensitive virological methods have revealed new viruses, and made it possible to find viruses in an increasing number of children with varying respiratory symptoms. Early sensitization to inhaled allergens, assessed by allergen-specific IgE or skin

prick tests, precedes clinical atopic symptoms and predicts also later asthma, and therefore belongs to the algorithm.

Early exposure to tobacco smoke seems to be justified to be included as a major risk factor, stressing the importance of the careful monitoring and treatment of wheezing children with tobacco smoke exposure also emphasizes the necessity of counseling against tobacco smoking, especially targeted to the mothers and fathers of tomorrow.

Flexible Fiberoptic Bronchoscopy in Children, Infants and Neonates

K Chugh

INTRODUCTION

Amongst the various technological advances, in the field of pulmonary medicine one of the prime examples which has been revolutionary, is that of flexible bronchoscopy.¹ In today's date, it has become one of the most frequently performed invasive procedures in pulmonary medicine.

A little more than a decade back the only indication and utility of bronchoscopy that was recognized by all pediatricians was removal of a foreign body from the airways. The instrument used was a metal tube through which a light could be reflected down into the airways and a forceps could be passed to hold the foreign body and remove it. The rigid scope has improved considerably in recent times. However, it still is made of a metal tube and can be passed into the tracheobronchial tree only under general anesthesia.

Flexible fiberoptic bronchoscopy (FFB) has indeed become an integral part of pediatric pulmonology, neonatology, critical care, laryngology, cardiothoracic surgery, etc. Even the anesthetists use these instruments.

Fiberoptic bronchoscopy allows inspection and biopsy of superficial airway structures, typically including epithelium, basement membrane, and lamina propria. Thus, mucosal structures and events can be studied, but the technique is less applicable to studies of smooth muscle.² In addition to visualization, bronchoscopes also provide an effective means to obtain specimens from the lungs and the airways.

SETTING UP A BRONCHOSCOPY UNIT

Bronchoscopy Suite

Any dedicated bronchoscopy suite should include space for patient preparation and recovery, a procedure area and a cleaning and maintenance area. FB does not require a surgical operating room or dedicated facility and can be

safely performed in many different areas, for example, a side room on a ward, an intensive care unit, fluoroscopy lab or neonatal ward, if adequate mobile equipment is available.

Personnel

The minimum personnel involved during bronchoscopy performed under sedation with local anesthesia are the bronchoscopist, an adequately trained nurse, and another trained person who is responsible for administration of sedation and for monitoring of the patient.

Instrumentation

The nomenclature of the sizes of bronchoscope can be confusing. In general rigid instruments are defined by the diameter of the largest instrument that will pass through the scope, while flexible bronchoscopes are defined by their outer diameter.³

The flexible bronchoscope is a solid instrument composed of thousands of glass fibers that carry the light for illumination and the image. The tip of the instrument can be deflected to guide it into the desired path or location.³

For children, the most important consideration is the size of the bronchoscope because of their narrow airways. Since the patient has to breathe around the flexible bronchoscope (unlike with a rigid scope), the flexible scope should not be more than two-thirds the diameter of the trachea. Thus, for neonates, flexible scopes with a diameter of around 2.5 mm and for infants 3.5 mm diameter scopes are used.

We have used Olympus bronchoscopes with outer diameter of 2.8 mm and 3.6 mm with a suction channel of 1.2 mm in them with ease. This size of the suction channel is sufficient to suck out secretions but is clearly a limitation for obtaining sufficient tissue for biopsy. Ultrathin bronchoscopes (e.g. 1.8 mm) are also available. However,

we have used the 2.8 mm scope for neonates even smaller than 1 kg with success on several occasions.

The most common instruments used with flexible bronchoscopes are flexible biopsy forceps and cytology or microbiology brushes. Small grasping forceps and folding retrieval baskets are also available.

Equipment

The instruments differ in terms of the length and diameter of the instruments and suction channel. Examples of the various types of pediatric flexible bronchoscopes commonly used are listed (Table 1).⁴

In general, the smallest bronchoscope available should be used, in order to ensure that the blockage of the airway is minimized, unless an endobronchial biopsy is to be performed. Here, there is an argument for the use of the instrument with the biggest available biopsy channel, provided it is safe for the child.

If the flexible bronchoscope is to be passed through an endotracheal tube, the recommended difference in diameter is at least 1 mm so that the instrument can move inside the tube without getting stuck or the bronchoscope being damaged.

The correct diameter of the flexible bronchoscope for pediatric use depends on the diameter of the child's cricoid cartilage,⁵ which is the narrowest point in the larynx. It is assumed that there must be at least a 2 mm difference

between the gauge of the bronchoscope and the diameter of the larynx in order to ensure that FB can be performed safely. In infants and children, the most frequently used instruments are those with an outside diameter of 2.8, 3.5 and 3.6 mm. From about the age of 6 years, instruments with larger diameters (4.9 mm) can be used, ultimately arriving at the bronchoscope used in adults (6 mm) by the time the child has reached puberty.

Mobile Bronchoscopy Unit

A mobile bronchoscopy unit permits the procedure to take place in any part of the hospital. A mobile cart has to be equipped with a bronchoscope, light source, ECG monitor and a pulse oximetry, video equipment and a suction device. The basic accessories (forceps, brushes, mucus traps, etc.) should also be stored in the cart along with the basic resuscitation equipment (endotracheal tubes, laryngoscopes, suction catheters, ventilation bag).⁶

Equipment Storage Area

Flexible bronchoscopes are expensive and fragile instruments that require delicate handling and storage to guarantee their reliable function for the maximum period of time.⁶

Flexible bronchoscopes should always be stored hanging in a straight vertical position to prevent development of unwanted curves of the shaft.

Table 1: Pediatric flexible bronchoscopes⁴

<i>Maximum diameter</i>	<i>Working channel*</i>	<i>Working length</i>	<i>Tip deflection</i>	<i>Field of vision</i>	<i>Depth of vision</i>
2.2 mm	Not present	550 mm	Up 160° Down 90°	75°	2–50 mm
2.8 mm	1.2 mm	550 mm	Up 180° Down 130°	95°	2–50 mm
3.5 mm	1.2 mm	600 mm	Up 180° Down 130°	95°	3–50 mm
3.6 mm	1.2 mm	550 mm	Up 180° Down 130°	120°	3–50 mm
4.9 mm	2.2 mm	600 mm	Up 180° Down 130°	100°	3–50 mm
5.0 mm	2.2 mm	550 mm	Up 180° Down 130°	120°	3–50 mm
3.8#	1.2 mm	600 mm	Up 180° Down 130°	120°	3–100 mm
4.9 mm#	2 mm	600 mm	Up 180° Down 130°	120°	3–50 mm
5.3 mm#	2 mm	600 mm	Up 180° Down 130°	120°	3–100 mm

#: Videobronchoscope; *: mm of maximum diameter

A dedicated storage cabinet is essential to avoid contamination. The cabinet should be easy to clean, and preferably no other equipment should be stored with the bronchoscopes, to avoid damage or contamination to the instruments.

It should be noted that flexible bronchoscopes should never be stored in an area routinely exposed to X-rays as this may damage the fiberoptic system.⁴

CARE AND MAINTENANCE OF BRONCHOSCOPES

Bronchoscopy is definitely not a sterile procedure, since the instruments pass through a non sterile area (the nose and/or the mouth).³

However bronchoscopes and all the associated instruments must be cleaned and sterilized before use in a patient,⁷ to avoid cross infection from one patient to another.^{8,9}

Flexible bronchoscopes are cleaned by careful scrubbing of the exterior with a soft cloth and enzymatic detergent, the suction channel by a cleaning brush, and the lenses scrubbed and polished with a soft cloth. Thorough rinsing is followed by high level disinfection^{10,11} (with glutaraldehyde or peracetic acid) or sterilization (with ethylene oxide).

PROCEDURE IN CHILDREN

Pre-requisites for flexible bronchoscopy in children are listed in Box 1.

Hospitalization

Hospitalization for flexible fiberoptic bronchoscopy is not necessary. In fact, the procedure can be performed on out-patient basis also. We have done FFB in as many as 37 percent cases on day-care basis whereby the patient is sent back from the hospital within 3 to 4 hours.

Box 1: Pre-requisites of FFB in children and neonates

- A clear indication for the procedure – where the risk/benefit is in patient's favor
- Appropriate instrument – size of the scope is the main consideration
- Facilities and skills for bronchoscopy in a child/neonate
- Facilities for monitoring the child clinically and with electronic monitors before, during and after the procedure
- Facilities and skills for cardiopulmonary resuscitation of the neonate/child in the event of a mishap
- Microbiology and cytopathology laboratory back-up for analysis of the broncho-alveolar lavage fluid
- Preferably, facilities for video-recording the bronchoscopic findings

Preparing the Patient

Details of the procedure and the discomfort that it may cause must be explained to the parents (and the child, in case of older children). Possible risks must be discussed with the parents, always emphasising the overall safety of the procedure. The child should be preferably fasting for the past few hours. Cooperation of an older child is best obtained by talking to him directly and establishing a rapport with him.

Anesthesia

No general anesthesia is used during FFB procedure in majority of the centers. Local anesthesia is given in the nose and pharynx using lidocaine instillation in the nose. As the bronchoscope is passed down into the pharynx more lidocaine is instilled through suction-cum-working channel of the bronchoscope, taking special care to spray adequate amount on the laryngeal structures. After waiting for a few minutes the bronchoscope is inserted down into the trachea. As we go down the bronchial tree, more lidocaine is sprayed all along, thereby suppressing the cough reflex and minimizing patient discomfort.

Premedication and Analgesia/Sedation During Procedure

Premedication with a sedative is commonly used before the procedure at many centers.¹² However, FFB has been performed at other centers without any premedication also.¹³ We used trichloryl/chloral hydrate in a dose of 50 to 80 mg/kg about an hour before the procedure routinely in the early phase of our FFBs. But, now we use sedation in only selected cases as we feel the procedure can be performed just as easily without the premedication sedation in a majority of cases.

Several choices are available for sedation and analgesia for FFB in children and neonates (Box 2). Although standard doses are known, the usual practice is to give a smaller dose initially and titrate the further doses according to the need.

Often FFB can be done in smaller children and infants without any sedation, using appropriate restraints so that the patient does not move too much during the procedure. While this may cause some discomfort and pain to the child, it enhances the safety of the procedure by avoiding the side-effects of the sedation-analgesia. It has been suggested that fentanyl, either alone or in combination with midazolam, should not be given to infants younger than 3 months of age for fear of respiratory depression or chest wall rigidity.

Positioning the Patient

Although the procedure can be performed in the sitting posture also, we prefer to do it with the child lying supine.

Box 2: Sedation and analgesia for FFB in children*Premedication*

Especially for apprehensive children in the age group 1 to 6 years

Chloral hydrate—in the dose of 50-80 mg/kg few hours before the procedure, orally

Local anesthesia

Used in all patients

2% lidocaine jelly/drops for nose

1% lidocaine for pharynx, larynx and tracheobronchial tree

Intravenous sedation +/- analgesia

Midazolam – 0.05 – 0.2 mg/kg

Morphine – 0.05 to 0.1 mg/kg

Pethidine – 1-2 mg/kg

Fentanyl – 1-3 mcg/kg (i.e. 0.001 mg/kg)

Ketamine – 1-3 mg/kg

Propofol – 2.5-3.5 mg/kg

Reversal agents

Naloxone – 0.01 – 0.1 mg/kg (max 2 mg)

Flumazenil – 0.01 mg/kg (max 0.2 mg)

This way it is easier to restrain the child's hands and feet by using small size bed sheets. We make the smaller children and infants lie down on a 'board' on which straps are tied across the child's chest and knees. One of the assistants manually restrains the head so that the child cannot move his head from side to side.

Precautions

Before starting the bronchoscopy resuscitative equipment and drugs are checked each time. Correct size endotracheal tubes, suction catheters, bag and reservoir, laryngoscope with appropriate blades and working lights, and correct size mask are kept in a tray within reach of the assistant. An extra suction machine/suction point should be available.

An intravenous line should always be placed and well secured before starting the procedure. We place an intravenous line well before the procedure in all cases (even those children who come 'walking in' for the bronchoscopy) to avoid causing pain by needle prick just before the bronchoscopy.

Oxygen by the other nostril (usually the left) is given in all cases as some degree of obstruction to the airways will inevitably be caused by the bronchoscope once it is passed below the glottis.

Finally, protection of the operator, assistants, nurses and any students is a must. Transmission of infection from the patient to the health personnel is possible through droplet inhalation, conjunctival inoculation or through minor cuts and abrasions on hands. Hence, gloves, goggles, gown, mask and cap are recommended. Hepatitis B protection by vaccine is also recommended. HIV transmission can only be guarded against by barrier methods.

Box 3: Flexible fiberoptic bronchoscopy in children*Routes of insertion*

- Nasal
- Through endotracheal tube
- Through LMA
- Through tracheostomy tube/stoma
- Through bag + mask assembly into the nostril (with ongoing positive pressure ventilation)
- Occasionally through mouth

Insertion of the Bronchoscope

In children nasal route of insertion is most commonly used. Other possible routes include the oral cavity, endotracheal tube, laryngeal mask or tracheostomy tube in cases where these tubes are already in place and sometimes through the rigid bronchoscope. When passing through the mouth there is always the danger of the patient biting on the scope thereby damaging the optical fibers (Box 3).

Negotiating the Larynx

Once the laryngeal structures have been examined the child's readiness for further insertion should be evaluated. This is done by checking adequacy of local anesthesia of the sensitive laryngeal structures and by checking that the child's oxygenation is well maintained. The tip of the bronchoscope is then gently moved downwards and the angle maneuvered carefully to cause minimum touching of the vocal cords. This will ensure that the child does not develop temporary hoarseness after the procedure. Evaluation of the subglottis is best performed at this stage.

During examination of the larynx extreme care has to be taken to avoid forceful coughing by the child. The dictum is "Never fight the vocal cords".

Examining the Tracheobronchial Tree

Having come past the glottis more lidocaine is sprayed and the bronchoscope advanced gently avoiding touching the walls of the trachea. All along the lower airways more lidocaine is required and same precautions are mandatory. The movements of the tracheobronchial walls are carefully studied to look for tracheomalacia and bronchomalacia. In the upper trachea often one is looking for that rare abnormality of H-shaped tracheoesophageal fistula in which a small opening may be seen along the posterior wall.

With experience the right and left main bronchi can be easily differentiated from each other. But, this differentiation is totally lost at the peripheral level where all subsegmental bronchi have the same appearances. The examination is carried out in a methodical, routine fashion to ensure no pathology is missed in any area. Any secretions must be delicately removed by suction and condition of the mucosa observed.

Manipulating the Fiberscope

Driving the fiber bronchoscope along the branching alleys of the bronchial tree may appear very easy at first sight but one tends to get lost inside, especially the beginners. A clear understanding of the anatomy, patience and gentleness are most helpful. The controls of the instrument, which are in the hands of the bronchoscopist, are very easy to manipulate but they can be mastered only by practice.

Monitoring

The child undergoing bronchoscopy is monitored closely during the procedure and for sometime after the procedure also. Heart rate, respiratory rate, oxygen saturation and end tidal carbon dioxide in intubated children is measured continuously throughout the procedure. A close watch is kept over the general condition of the child, color, pulse and type of respiration. Child is observed closely at least till he comes out of the heavy sedation (if used). Any bleeding, stridor or sudden deterioration in general condition is looked for.

INDICATIONS FOR FFB

Upper Airway

- Stridor
- Persistent hoarseness
- Postintubation problems
- Nasal obstruction
- Sleep-associated airway obstruction
- Suspected vocal cord paralysis
- Aspiration
- Nasotracheal intubation
- Difficult endotracheal intubation
- Epistaxis (not explained by anterior nasal findings).

Lower Airway

- Atelectasis
- Unexplained/Persistent/Localized wheeze
- Suspected foreign body (but not certain, equivocal)
- Post foreign body removal evaluation
- Recurrent pneumonia
- Interstitial pneumonia
- Suspected congenital anomalies
- Hemoptysis
- Suspected airway compression
- Unexplained, disturbing chronic cough
- Removal of excessive bronchial secretions
- Evaluation of airway in tracheostomy patients
- Confirmation of endotracheal tube position
- Assessment of thermal or chemical/toxic inhalational damage to the airway.

Radiographic Abnormalities

- Atelectasis
- Recurrent/Persistent consolidations
- Atypical and unknown infiltrates
- Localized hyperinflation
- Selective bronchography (rarely required).

Therapeutic Indications

- To remove mucus plugs or blood clots
- Restoration of airway patency
- To remove excessive secretions in the lower airways
- Alveolar filling disorders (alveolar proteinosis, lipid pneumonia).

Special Procedures

- To perform therapeutic BAL
- Endotracheal intubation
- Laser therapy of lesions obstructing the lower airways
- Guide to surgical interventions
- Plastic bronchitis of acute chest syndrome
- Brushing or biopsy of the bronchial mucosa
- Biopsy of endobronchial lesions
- Transbronchial biopsy
- Administration of drugs.

EXPERIENCE WITH FFB IN PEDIATRICS

In some of the centers in USA pediatric FFB started more than three decades back. By 1987, Reddy and Vauthy from Ohio¹³ had performed the procedure in over 4,000 cases. Wood had performed FFB in over 3,000 cases by 1992.¹² Similarly, Fan has been working with the flexible bronchoscope since at least 1981¹⁴ and Deblic reported therapeutic applications of FFB in pediatrics as early as 1984.¹⁵ Recently Nussbaum has published his 20 years experience with pediatric fiberoptic bronchoscopy (Box 4).¹⁶ In India too FFB was started by Somu and colleagues at Institute of Child Health, Madras (Chennai), Tamil Nadu, India quite early. They reported their experience of 630 cases from January 1989 to August 1995. However, only 12.3 percent of their patients were less than 4 years old and the youngest was 50 days. In our institution almost half (48%) of the children were less than one year age (Tables 2 to 6).¹⁷ In the Madras study almost 30 percent of the children had bronchiectasis, a condition that we see very seldom in young children at our center. In the Madras study no comment has been made about the dynamic problems of the airways. We encountered significant laryngomalacia in 22 percent, bronchomalacia in 14 percent and tracheomalacia in 5 percent cases (Tables 3 and 4).¹⁷ Nussbaum's series had 19 percent of subjects below 12 months age and the pathology diagnosed had a similar spectrum as ours.¹⁶

Box 4: FFB in children: How is it different

1. Smaller size of the airway does not leave sufficient space around the scope for breathing. Consequent hypoxia and hypercarbia are minimized by using smaller size scope, administering oxygen during the procedure and finishing the procedure in the shortest possible time.
2. Indications for FFB are different. Tumors are rare. Congenital malformations are more common.
3. Problems of upper airway are often the indication, e.g. stridor.
4. Dynamic problems of airway, e.g. laryngomalacia, bronchomalacia and tracheomalacia are important considerations.
5. Children can be restless, anxious and even combative. Adequate analgesia and sedation is required.
6. Biopsy is not commonly required. A study of the cytology of BAL is considered as a "liquid biopsy".
7. Transbronchial lung biopsy is rarely done; mainly because lung pathology requiring this procedure is uncommon in children.

Table 2: Age and sex distribution of FFB cases (Jul 1993 to August 2006)¹⁷ (n = 3226)

Age	No. of procedures	Percentage
<1 month	258	8%
1-3 months	580	18%
3-12 months	709	22%
1-5 years	1000	31%
>5 years	420	13%
>10 years	259	8%
Total	3226	100%
	M-57%	F-43%

Non-PICU	2613 (81%)

COMPARATIVE ANALYSIS OF INDICATIONS AT SGRH AND TERTIARY REFERRAL CENTER (TABLE 7)

Comparing the indications for doing FFB in GRH and at a tertiary care referral center in New Delhi, most common indication in both the studies was nonresolving pneumonia.^{17,18} Other indications being stridor, foreign body in GRH study, and persistent collapse in the other study.

EVALUATIONS IN DIFFERENT CONDITIONS**Evaluation of Upper Airways and Larynx**

When the flexible scope is being passed through the nose and pharynx the bronchoscopist has an opportunity to examine these areas. Problems like choanal atresia and choanal stenosis are detected and evaluated.

However, the area of maximum interest to the pediatrician is usually the adenoids, larynx, the supraglottic structures, the vocal cords and glottis and the subglottis. Care and patience during examination of laryngeal area along with video recording (for possible review later) greatly enhance the diagnostic value of FFB. This also gives the opportunity to study the laryngeal structure and function during inspiration and expiration.⁴

Stridor or noisy breathing, that usually reflects an obstruction of the upper airways, is the most common indication for FFB in infants.⁴

Other congenital anomalies of the larynx causing stridor are: laryngoceles and saccular cysts, laryngeal webs and atresia, laryngotracheal stenosis, laryngeal and

Table 7: Comparative analysis of indications in 2 studies^{17,18}

Indications	GRH (n=3226)	AIIMS (n= 529)
Nonresolving pneumonia (NRP)	11%	41.77%
NRP in immunocompromised	–	4.91%
Inflammation	25%	–
Outside pressure on airway (Tracheal compression)	12%	–
Stridor	–	10.01%
Foreign body	24%	–
Vocal cord palsy	0.5%	–
Post-tracheostomy evaluation	11%	–
Normal FFB	24%	–
Bronchomalacia	14%	–
Mucopurulent plugs	10%	–
Resistant TB?	–	7.56%
Subglottic stenosis/edema	17%	–
Hemoptysis	–	7.93%
Pulmonary agenesis/H-type TEF	–	1.89%
Cystic fibrosis	–	6.4 %
Persistent collapse	–	15.5%
Interstitial lung disease	–	4.53%

tracheal clefts, congenital neoplasms such as hemangiomas, bifid epiglottis and ventral cleft of the larynx.¹⁹

Laryngeal cleft may be missed by FFB, and rigid bronchoscopy should be performed if this diagnosis is seriously considered.⁴ Abnormalities below the epiglottis were found in up to 68 percent of cases.²⁰

Laryngomalacia and paralysis of vocal cords are two most common abnormalities of the larynx besides laryngeal stenosis, congenital web, etc. The movements of vocal cords with each respiration and during phonation should be observed carefully. Nussbaum detected 14 cases of vocal cord dysfunction in his series of 2,836 cases.¹⁶ Paralysis of vocal cords and scar tissue formation may interfere with the movements of the cords.

Laryngomalacia is well studied by the flexible scope. The size, shape and floppy nature of the arytenoids, epiglottis and the aryepiglottic folds can be assessed during spontaneous quiet breathing (in well-sedated child) and during crying/ activity, etc. This is helpful in therapeutic decision making. Not all cases of laryngomalacia are benign and mild. We have performed tracheostomy for this indication and have seen a death occur after the diagnosis was made but tracheostomy refused by the parents in another child.

Evaluation of cases of croup before intubation, at the time of attempted extubation, at failed extubation, at time of deciding for tracheostomy and at the time of attempt at decannulation of tracheostomy has been advocated.²¹ Diagnosis of bacterial tracheitis by FFB can be very helpful in croup.²² Subglottis is crucial in cases of pathology in laryngeal area, especially in postintubation patients. Subglottic edema, congestion, mucosal injury, narrowing and granulation formation are the common abnormalities encountered. Failure to or difficulty in negotiating this area during endotracheal intubation is an indication for bronchoscopic evaluation.

Evaluation of Tracheostomy

Once a tracheostomy tube has been inserted, the child may require repeated bronchoscopic examinations of the larynx and lower structures to evaluate their present condition and possible readiness for decannulation. Granulation tissue at the stoma obstructing the trachea or in lower trachea may develop in such children. The anterior wall of the trachea at the site of stoma may move posteriorly, thereby narrowing the airway.¹²

When the main pathology was in the larynx, say stridor, the bronchoscope is passed through the nose and supraglottic structures, vocal cords and the subglottic space evaluated. If these are assessed to be better and child ready for decannulation the scope should be passed further down (after removing the tracheostomy tube if it cannot be passed by its side). This way the lower airways are also examined.

Sometimes, the bronchoscope can be passed through the stoma by the side of the tracheostomy tube without removing it. Passing the scope through the tracheostomy tube may be easier, unless the tube size is too small.

If the examination of the uppermost part of trachea is not possible through the glottis because of severe narrowing there, the scope can be passed retrograde through the tracheostomy stoma and the extent of subglottic narrowing evaluated. We have done this a few times and found it to be very useful.

Dynamics of Lower Airways

Collapse of the walls of trachea and/or bronchi during expiration is a common acquired abnormality in infants and young children (tracheomalacia and bronchomalacia). Many children who continue to have 'wheeze' after extubation are suffering from these conditions. Naturally, they respond poorly to anti-asthma treatment. Occasionally, the condition may be severe enough to result in hypoxemia, sleep disturbances and apnea.

Tracheomalacia and Bronchomalacia

Congenital malacia of the large airways is one of the few causes of irreversible airways obstruction in children, with symptoms varying from recurrent wheeze and recurrent

lower airways infections to severe dyspnea and respiratory insufficiency.²³⁻²⁶

Severe cases are usually detected in the neonatal period when children present with ventilator dependency or acute severe obstructive episodes with cyanosis.

Children with mild airway malacia often present after the neonatal period with nonspecific symptoms such as rattling, wheeze, stridor, exercise intolerance, cough, recurrent lower airway infections, and airways obstruction.^{25,27}

Primary airway malacia is defined as airway malacia in otherwise normal infants.²⁷ Secondary airway malacia was defined as airway malacia secondary to esophageal atresia, VATER/ VACTERL association (condition with vertebral anomalies, anal atresia, congenital heart disease, tracheoesophageal fistula or esophageal atresia, renourinary anomalies, or radial limb defects), vascular or other external compression of the airways, or specific syndromes.

Malacia was defined as collapse of at least 50 percent of the airway lumen, during expiration, cough or spontaneous breathing, or a ratio of cartilage to membranous wall area of <3:1.²⁷

Primary airway malacia is common. Ruben Boogaard et al reported its incidence to be 1 in 2,100.²⁸ As a correct diagnosis is important because of the therapeutic implications and perhaps lifelong consequences, bronchoscopy should be done in all patients with unexplained exercise intolerance, recurrent lower airways infection, and irreversible and/or atypical asthma.²⁸

Chronic Cough

Pediatric chronic cough is defined as a daily cough lasting for >4 weeks. Chronic cough is subdivided into specific cough (i.e. cough associated with other symptoms and signs suggestive of an associated or underlying problem) and nonspecific cough (i.e. dry cough in the absence of an identifiable respiratory disease of known etiology).²⁹

Chronic cough (atypical and persistent) in a patient with normal imaging, functional studies and hematological examinations, and that does not respond to medical therapy is another indication for flexible endoscopy in children.^{4,30}

ACCP evidence-based guidelines recommend FFB for following indications:

- Suspicion of airway abnormality,
- Localized radiology changes,
- Suspicion of an inhaled foreign body,
- Evaluation of aspiration lung disease, and
- Microbiological studies and lavage.²⁹

Stridor: Clinical Condition

Stridor in children indicates anatomical or functional obstruction of the upper airways. Age of presentation, besides the other clinical features can be a useful diagnostic clue. For example, laryngomalacia is the commonest cause of stridor in early infancy. If the stridor is mild and

classical features are present a clinical diagnosis of laryngomalacia can be made with reasonable certainty. However, if the obstruction is severe or atypical features are seen, a bronchoscopic evaluation of upper as well as lower airways should be done. Approximately, one-sixth of cases of laryngomalacia were associated with lower respiratory tract abnormalities in a large series.

Common Diagnostic Entities in Children with Stridor

- Congenital malformations of supraglottic, glottic, subglottic structures, trachea
- Post-extubation edema/inflammation
- Severe laryngomalacia, tracheomalacia
- Tracheoesophageal cleft
- Foreign body
- Vascular ring (e.g. double aortic arch)
- Infections, e.g. retropharyngeal abscess, diphtheria
- Hemangioma
- Laryngotracheal angioedema.

Bilateral Wheeze

Besides asthma, the following conditions can result in bilateral wheeze. When there is no response to anti-asthma treatment or there are other clues to the diagnosis (clinical or radiological), flexible bronchoscopy can be a useful tool in the evaluation of such a child.

Causes of Bilateral Wheeze in Children

- Tracheomalacia – primary or secondary
- Bronchomalacia – primary or secondary
- Stenosis
 - with complete tracheal rings
 - without complete tracheal rings
 - post-traumatic, e.g. postintubation, postburns
- Vascular ring compressing the trachea
- Foreign body at carina/in trachea
- External compression of trachea
 - enlarged lymph nodes
 - cardiac chambers
 - mediastinal cysts, masses
- Endobronchial tuberculosis, both sides
- Bronchiectasis
- Neoplasms, hemartomas
- Tracheal candidiasis.

Unilateral Wheeze

Persistent wheeze on one side or only in a localized area indicates a localized obstructive pathology. Such a patient is likely to benefit greatly by flexible bronchoscopy in diagnostic evaluation.

Unilateral/Localized Wheeze

- Foreign body
- Endobronchial tuberculosis

- Compression of bronchus from outside by
 - lymph nodes
 - mediastinal mass
 - vascular ring
 - cardiac chambers
- Bronchial stenosis
 - congenital
 - acquired, e.g. postintubation and vigorous tracheal suction
 - Congenital lobar emphysema
 - Endobronchial tumor.

Bronchial Asthma

Patients of bronchial asthma who respond poorly to steroids should undergo bronchoscopy and endobronchial biopsy.

Biopsy evidence of steroid resistant eosinophilic inflammation in a symptomatic child, with features of basement membrane thickening and increased smooth muscle, confirms asthma, and strengthens the argument for use of further anti-inflammatory therapy, such as cyclosporine.

Conversely absence of typical pathological features would help to take a reappraisal of diagnosis and treatment.³¹

Recurrent/Persistent Preschool Wheezers

Management of severe, recurrent wheezing is often difficult in infants and preschool children, particularly in those children who are refractory to conventional asthma therapy.

In such cases other diagnosis must be excluded. In a study conducted by S Saglani et al, children aged between 3 months and 5 years with severe recurrent wheezing, underwent a protocol of investigations including a chest computed tomography scan, blood tests, nasal ciliary brushings, fiberoptic bronchoscopy, bronchoalveolar lavage (BAL), endobronchial biopsy and passage of an esophageal pH probe.³²

The study revealed abnormal results in three-quarters of cases. Findings included atopy in 39 percent, two-thirds had evidence of gastroesophageal reflux, structural abnormalities (13 out of 37), excessive mucus (20 out of 37) and macroscopic inflammation (10 out of 37). BAL revealed bacterial growth in 12 out of 44 (27%) patients. Good quality endobronchial biopsies were obtained from 36 out of 46 (78%) patients; of these, 44 percent had tissue eosinophils and 28 percent had a thickened reticular basement membrane.³³

FFB in Immunocompromised Child

Detection of opportunistic organisms in the BAL in immunocompromised host (e.g. HIV, antimalignancy treatment, congenital immunodeficiency disorders) is a very rewarding experience as it helps in planning the specific treatment.^{32,34-39} The child with unexplained radiological opacity may be an immediate beneficiary sometimes

when an endobronchial tubercular lesion is detected or when *Mycobacterium tuberculosis* is identified on Ziehl Nelsen staining or by fluorescent techniques. Cultures of *M. tuberculosis* and its sensitivity tests with antitubercular drugs is another step that is critical in decision making regarding the specific antitubercular drugs to be used in such children.

However, the commonest pulmonary infections even in the immunocompromised host are due to the usual pathogens like *Pneumococcus*, *Staphylococcus*, etc. When these organisms are cultured with high colony counts and associated with a strong polymorphonuclear response in BAL fluid the clinician can choose the suitable antimicrobial drugs, especially when resistant strains are the offending agents.

In a study⁴⁰ conducted at Sir Ganga Ram Hospital, New Delhi, India, 30 children (age range 10 mon-14 yrs) with neutropenia (absolute neutrophil count less than 1500/cumm) and pulmonary infiltrates were subjected to BAL by FFB. All the cases had been on antibiotics without an adequate response. Four children showed *Pneumocystis carinii*, four fungus and two tuberculosis. Pyogenic pathogens were isolated in eight patients. A number of other studies have shown BAL to be a useful procedure in immunocompromised children.⁴¹

All the children tolerated the procedure well in GRH study except one who developed increased hypoxemia for a short while. Safety of the procedure, especially the low incidence of hemorrhage, in immunocompromised children has been emphasized in a review.⁴¹

A study conducted by Ori Efrati, which included a large number of immunosuppressed and patients of congenital heart disease, revealed that FFB and BAL contributed to a specific diagnosis in 79 percent of the patients.⁴²

Role of FFB in Pulmonary Tuberculosis

Suspected pulmonary tuberculosis is ordinarily not an indication for FFB. However, when the response to treatment is not adequate, radiological opacities persist, atelectasis does not clear, gastric lavage fails to show acid-fast bacilli,⁴³⁻⁴⁶ FFB may prove useful. When differentiation from a non-responding pyogenic pneumonia or a foreign body aspiration is not clearly possible by other noninvasive investigations.

FFB should be done. Since children cannot produce sputum confirming MDR tuberculosis is not easy. FFB provides an opportunity to examine the airways as well as obtain a sample for bacteriological examination. Endobronchial tuberculosis lesions can be identified on FFB examination. Their brushings or bronchoalveolar lavage cytology may show the specific cells. In older children it may be possible to take a biopsy also. Further, the specific organism may also be demonstrated.

FFB and BAL in Nonresolving Pneumonia in Immunocompetent Children

Persistent pneumonia which has not responded to the apparently correctly chosen antimicrobial treatment is not an uncommon situation in hospital practice. In the majority of such children there is no reason to believe that they have any immunodeficiency. There may not be enough evidence to label that pneumonia as tubercular either. In such cases after sufficient trial has been given or if the situation is deteriorating in spite of the well-chosen antimicrobials or if radiological/clinical features suggest the possibility of unusual/resistant organism FFB and BAL should be done.

In our experience FFB may help in diagnosis of an unexpected foreign body; compression of a bronchus, lung abscess missed on chest X-ray and computed tomography, etc. Further, BAL performed in these cases may yield a fungus, resistant bacteria (*Staphylococcus aureus* is not an uncommon pathogen), *Pneumocystis carinii*, etc. as the possible pathogen (thesis). Rock (1995) also found BAL to be useful in selected patients of nonresolving pulmonary infiltrates in immunocompetent children.⁴⁷

Many of the organisms identified in BAL fluid are also the commensals of upper respiratory tract through which the bronchoscope inevitably passes and contamination invariably occurs. To increase the specificity of BAL fluid cultures in diagnosing common bacterial pneumonia the concept of quantitative.

BAL cultures were introduced on the lines of urine culture colony counts. Using such quantitative cultures cut-off points of 10^4 or 10^5 colony forming units (cfu)/ml have been suggested in the literature.⁴⁸⁻⁵⁰ Our own studies⁵¹ have shown 10^4 cfu/ml to be a useful cut-off value between possible commensals and pathogens.

Aspiration Pneumonia

Children with suspected aspiration pneumonia may benefit from FFB. Tracheoesophageal cleft, H-type tracheoesophageal fistula, etc. can be diagnosed. Techniques for identifying the H-fistula using methylene blue dye have been described. Some children have frequent lower respiratory tract infections following repair of congenital tracheoesophageal fistula (TEF) with a tracheal character cough and/or wheeze. FFB evaluation of such children may yield tracheomalacia in the repaired segment, stenosis or just irregular architecture of the mucosa in this segment. Rarely, there may be a recurrence of the fistula or an incomplete repair may be the cause for recurrent aspiration pneumonia. Damage caused by repeated episodes of aspiration pneumonia can also be evaluated.

Atelectasis

Atelectasis of the whole lung, a lobe or a segment is a common condition encountered in the NICU, PICU and the

postoperative wards. This is often due to mucus plugs or mucopurulent thick secretions or granulations caused by suction catheter/endotracheal tube trauma. Sucking out of the mucus plugs proves useful in a number of such children, especially when hydration, humidification, nebulization, vibrations and chest physiotherapy have failed. Removal of the mucus plug may have an effect akin to removing the cork out of a bottle, i.e. opening a closed bronchus and allowing the relevant part of lung to expand immediately. However, the results are not as dramatic most of the times. Bar-Zohar and Sivan reported a success rate of 74 percent of treating lung atelectasis by FFB and lavage.⁵²

Bronchial stenosis, a mass lesion within the bronchus or compression of the airways from outside may be the cause of atelectasis. Some of these problems have not only been evaluated by FFB but even treated using laser.

Role of FFB in PICU

From July 1993 to January 1996, FFB was carried out 108 times in patients in the PICU in our institution. Majority of the patients were below 2 years age (69%), with the youngest child being 2 days old. Minimum weight of the child undergoing bronchoscopy was 1.5 kg. Males predominated. Common indications for FFB were stridor (16%), suspected foreign body (23%) atelectasis (24%), nonresolving pulmonary infiltrates (29%) and persistent or atypical wheeze (11%) (Table 8). In six cases, nasotracheal intubation was carried out with the aid of the bronchoscope.

Frequent findings included purulent material in airways, mucopurulent plugs, severe laryngomalacia,

Table 8: Indications for FFB in PICU: (July 1993 to Jan 1996)⁵³

Indications	July 1993-199 (n = 108)	Sept 2005- Oct 2006 (n = 140)
Stridor	16%	14.28%
Suspected foreign body	23%	11.42%
Atelectasis	24%	74%
Nonresolving pulmonary infiltrates	29%	—
Persistent or atypical wheeze	11%	—
Nasotracheal intubation	6	
Persistent lung collapse	—	53.57%
Assessment of airway for pathology	—	35%
Abnormal airway pathology/anatomy	—	9.28%
BAL	61%	46.42%
ET	—	14.28%
Mixed	—	23.57%

tracheomalacia, foreign body, postintubation granulations and tracheobronchomalacia.

Bronchoalveolar lavage was performed in 68 (61%) procedures and proved useful in planning further treatment in all these cases.

FFB was helpful in evaluation airways in all patients. It helped in clearing the airways of blocking secretions or plugs in 32 (29%) procedures. In two cases foreign material (thin peel of groundnut in one case and forcibly fed 'meal' in another case) was sucked out and rigid bronchoscopy was avoided. In all other cases of foreign body removal was carried out under general anesthesia by rigid bronchoscopy in the operation theater. Minor complications occurred in 11 percent patients, commonest being transient dip in oxygen saturation. No major complications were encountered.

Another retrospective study was done between September 2005 to October 2006 in our institution. One hundred and forty procedures were performed, out of which 120 (86%) were intubated. The common indications were persistent lung collapse 75 cases, assessment of airway for pathology,⁴⁹ (upper airway obstruction,²⁰ suspected foreign body,¹⁶ abnormal airway pathology/anatomy¹³), to obtain broncho-alveolar lavage,⁶⁵ to confirm position of endotracheal tube-20, and mixed indications.³³ No procedure related mortality, life-threatening complications, or significant changes in patient status occurred.⁵³

Role of FFB in VAP

Children on the ventilator often develop new opacities in their lungs when on the ventilator, especially when ventilation is prolonged. Identifying the causative organism of ventilator associated pneumonia and choosing the appropriate antibiotic can be crucial. Endotracheal suction, blind bronchial sampling (BBS), 'blind' bronchoalveolar lavage and FFB assisted BAL are the techniques employed for obtaining the 'secretions' from the lower airways. In a study, we compared these four techniques in children with VAP. Blind bronchoalveolar lavage was the most reliable method followed closely by blind bronchial sampling for the diagnosis of ventilator-associated pneumonia. Considering the difference of the cost in the two procedures, blind bronchial sampling may be the preferred method in the pediatric intensive care unit of a developing country.⁵⁴

FB in Neonates

The first fiberoptic bronchoscope that was useful in neonates was the 3.5 mm Olympus bronchoscope with a 1.2 mm suction channel. Later, even smaller diameter scopes (up to 1.8 mm) with flexible tips have been developed and are being increasingly used in evaluation of pulmonary pathology in newborns.⁵⁵ We have performed bronchoscopy with or without BAL in a fairly large number of newborns using 3.5 mm and 2.8 mm Olympus

bronchoscopes. The smallest size baby was 900 gram pre-term. Taking all the appropriate precautions we have not encountered any major complications. Nor is the rate of minor complications much higher in this age group. Yes, the time for which the bronchoscope can be kept below the glottis in very small babies has to be limited and the bronchoscope withdrawn at the earliest indication of a significant problem, like desaturation on pulse oximeter. Supplemental oxygen is essential in all cases.

Indications of bronchoscopy in newborns are discussed below and the yield of FFB in the common indications from a reported series are summarized in Table 9.⁴¹

Urgent Indications

Suspected airway obstruction in intubated neonate

The obstruction may be in the tube, at its lower end or even beyond. Usually, the cause is thick secretions/mucus plugs. These can be sucked out, thereby obviating the need for tube removal and reintubation.

Suspected dislodgement of the endotracheal tube

This is also best handled with the help of FFB.⁵⁶ In fact, it has been the experience of many at the highly specialized neonatal units that confirmation of the position of lower end of the endotracheal tube by FFB takes less than 60 seconds while a portable X-ray film takes much longer. This time period may be crucial for a newborn with acute severe deterioration. Indeed, Vigneswarm and Whitefield⁵⁷ showed that bronchoscopy resulted in lesser desaturation than radiography and was also more accurate.

Evidence of airway obstruction after extubation

This is a common phenomenon. Quickly performed FFB can detect problems like laryngeal edema, vocal cord paralysis, prolapsing laryngeal structures, mucus plugging or simply posteriorly falling tongue. Fan et al⁵⁸ in 73 consecutive postextubation laryngeal evaluations found a 44 percent incidence of moderate or greater laryngeal injury. Fan et al⁵⁹ and Sherman et al⁶⁰ studied the risk factors for postintubation subglottic stenosis. They suggest that stridor after extubation is a strong indication for bronchoscopy.

Table 9: Diagnostic yield from flexible bronchoscopic procedures in the neonatal period based on indications for bronchoscopy⁴¹

Indication	Diagnosis made/number of procedures (%)
Stridor	52/54 (96)
Acute respiratory distress	9/36 (25)
Congenital anomalies	5/7 (71)
Bleeding	2/2 (100)
Wheezing	24/26 (92)
Atelectasis/Emphysema	28/35 (80)

Vaughy and Reddy

Vaughy and Reddy⁶¹ have pioneered the technique of intubating newborns using the flexible bronchoscope in difficult cases, e.g. hypoplastic mandible or maxilla, hydrocephalus or other malformations.

Such intubations being nasotracheal are more useful. With experience this type of intubation can be done in a very short time.⁵⁶

Elective Indications

- Determination of position of distal tip of an intubated infant has been shown to be reliably confirmed by FFB. The time taken by Dietrich et al⁵¹ was 40 seconds compared to 30 minutes for X-ray
- Stridor or other signs of airway obstruction
- Recurrent atelectasis associated with intubation or following extubation to determine if there are tracheal abnormalities, e.g. tracheomalacia, tracheobronchomalacia
- Persistent localized emphysema
- Focal wheezing
- Wheezing not responding to bronchodilators.

Unusual Indications

- Severe unilateral pulmonary interstitial emphysema
- Persistent unilateral airleaks.

Special Precautions in Preterms and VLBW Newborns

- Avoid disturbing the newborn too much. Perform the procedure in NICU itself
- Oxygenate well throughout the procedure
- When already on ventilator increase FiO₂ to 100%
- Suction very gently and for minimum duration
- Use sedation/analgesia carefully
- Always use adequate local anesthesia
- Use smallest size bronchoscope that will serve the purpose. For most diagnostic work 2.2 mm ultrathin bronchoscope is preferred
- Interrupt the procedure as soon as significant problems like desaturation are noticed
- Perform the procedure in blocks keeping the bronchoscope below the larynx for a maximum of 30 to 40 seconds in one block.

Role of FFB in NICU

We have performed this procedure in a large number of NICU patients, sometimes at the bedside and at other times by shifting them to the bronchoscopy suite.

Age of neonates undergoing the procedure ranged between 1 and 78 days and the weight between 0.9 and 3.6 kg. Unexplained severe stridor, clinical evidence of lower airway obstruction, postintubation/ventilation evaluation of airway, unexplained and persistent pulmonary opacities and atelectasis were the common indications. Evaluation of the airways for a suspected congenital

anomaly is the most frequent indication in the early neonatal period.

Laryngomalacia severely obstructing the airways, tracheobronchomalacia, purulent material in lower airways, mucopurulent plugs, postintubation/endotracheal suctioning granulations and unilateral choanal atresia were the endoscopic findings observed.

Experience of Finer⁵⁶ with neonatal FFB is summarized in Table 10.

FFB with LMA

Laryngeal mask airway (LMA) of pediatric and neonatal sizes have now become available and are proving to be a useful adjunct in FFB. When the size of the endotracheal tube being used for an infant is less than 4 mm, it is not safe to pass a 2.8 mm bronchoscope through it. In such situations, the endotracheal tube can be removed temporarily and replaced by a LMA. The bronchoscope can then be passed through the LMA. When the LMA is properly positioned, entry into the trachea is easily achieved. However, there is some limitation in evaluating the supraglottic structures when the scope is passed through a LMA. We have been very satisfied with LMA in a large number of cases that we have used it. Nussbaum has also found LMA as a good alternative.¹⁶

TYPES OF BRONCHOSCOPIES

Diagnostic Bronchoscopy

Bronchoalveolar Lavage

In 1978, the Olympus company introduced a flexible fiberbronchoscope for use in pediatric patients.⁶² Within the next decade, its use for performing BAL in pediatric patients was described by many pulmonologists.^{32,34,35}

Table 10: Neonatal fiberoptic bronchoscopy⁵⁶

Diagnosis	Number
<i>Upper airway</i> (N = 144)	
• Laryngomalacia	45
• Subglottic narrowing	
– Edema, web, stenosis	16
• Vocal cord paralysis	
– Unilateral or bilateral	11
<i>Lower airway</i> (N = 220)	
• Tracheomalacia	28
• Bronchomalacia	10
• Tracheal/bronchial	
– Granulations	42
Obstructed/dislodged	
– Endotracheal tube	18

N = 220; via endotracheal tube = 76; transnasal, nonintubated = 144; bronchoscopic intubations = 40

BAL can be defined as the instillation into and recovery from the distal airways of a volume of saline sufficient to ensure that the fluid returned contains at least some fluid that was originally present on the alveolar surface.³ Both soluble and cellular constituents of the alveolar (and small airway) surface fluid are contained in the effluent. As an extension of fiberoptic bronchoscopy, bronchoalveolar lavage adds only 3 to 5 minutes to the procedure and has been shown to be relatively safe, with a reported complication rate of <0.4 percent in the largest series of 1095 children described by Wood et al.⁶³ Besides, FFB can be done safely and effectively using topical anesthesia, unlike rigid bronchoscopy for which general anesthesia is virtually mandatory.⁶⁴

BAL^{65,66} yields a specimen that can give representative data from the distal airways and alveolar surfaces. As in adults, BAL has been used in children in the investigation of noninfectious interstitial lung diseases and in the identification of infectious agents.⁶⁷ By far the major application of BAL in the pediatric population has been the diagnosis of infection, particularly in the immunocompromised host.^{32,34-39} Perhaps the best recognized indication is the diagnosis of *Pneumocystis carinii* pneumonia in such children.^{39,68}

The main principle of BAL is to obstruct an airway with catheter and flood the airways and alveolar spaces distal to that site with saline. The airway must be occluded, or the instilled fluid will spill into adjacent airways, resulting in coughing, possible respiratory embarrassment and loss of returned volume. BAL may be performed with a rigid bronchoscope by advancing a catheter beyond the tip of the bronchoscope into the desired location. A flexible bronchoscope, however, is more ideally suited for BAL, since its tip is maneuverable and can be easily directed to and wedged into the desired bronchus. Besides increasing the range of visualization of the peripheral airways, this permits the tip to be wedged in the smaller airways. The volume of lung lavaged will depend on the size of the catheter or bronchoscope in relation to the size of the airway. For example, the standard 3.5 mm pediatric flexible bronchoscope will wedge into a segmental airway in a newborn infant and into a sub-subsegmental airway in an 8-year-old child.⁶⁴

After passage of the bronchoscope intranasally and a general inspection of the airways, a lung subsegment is selected for lavage. In the absence of a localized abnormality in the X-ray or on direct visualization, the right middle lobe or lingular bronchus is usually selected.⁶⁷

Small aliquots 3-4 ml/kg divided into three aliquots with a maximum of 20 ml per aliquot,^{69,70} of sterile normal saline are instilled through the suction channel. The fluid sucked back a little later gets mixed with the secretions and fluids in the wedged area of the lung and is collected in a sterile chamber. This is then analysed in the microbiology and cytopathology laboratories.

Bronchial brushing, commonly used in adults, is not feasible in younger children and infants because of limitations of size of the bronchoscope. However, the microbiology brush can be easily used in children more than 4 years age⁷¹ and sometimes in younger children also.

Bronchial Washings

The utility for bronchial washings is largely for the diagnosis of airway diseases including fungal or mycobacterial infection.¹

Endobronchial Biopsy

This is basically used for lesions directly visualized during bronchoscopy. It provides histological specimens whereas bronchial washing provides only cytological samples.

Indications

- Diagnosis of tuberculosis and other infectious or granulomatous disorders
- To obtain ciliated cells for the diagnosis of primary ciliary dyskinesia
- Research applications include studies on bronchial inflammation in patients with asthma or cystic fibrosis.⁷²⁻⁷⁶

Transbronchial Biopsy

Transbronchial biopsy (TBB) is a technique to obtain peripheral lung tissue for diagnostic studies including histopathological examination and for microbial cultures.

Indications

- TBB has an established place in lung transplant recipients: It has a high sensitivity and specificity, and represents the gold standard for diagnosing acute rejection and delineating opportunistic infection⁷⁷
- It is of less use in diagnosing chronic rejection (bronchiolitis obliterans)⁷⁸
- In patients with human immunodeficiency virus (HIV) infection to delineate noninfective pulmonary pathology
- After bone marrow transplantation to diagnose obliterative bronchiolitis
- In patients with interstitial lung disease.⁷⁹

Fluoroscopy is mandatory for accurate positioning of the biopsy forceps in order to get the maximum yield from sites of radiographic abnormality and to minimize the risk of pneumothorax.

A chest radiograph 2 to 4 hours later is mandatory to rule out a slowly developing pneumothorax. Only one lung should be sampled on a same occasion in order to prevent the occurrence of bilateral pneumothoraces.

Complications

- The major complication of TBB is a pneumothorax with an incidence of ~3% in adults
- Small hemorrhages often occur but resolve either spontaneously or after lavage with saline. If bleeding is

profuse and persistent; instillation of adrenaline solution (1:10,000) may be necessary

- Transient pyrexia
- Transient dyspnea.

Thus, it is recommended that patients should be observed overnight following the procedure.

Transbronchial Needle Aspiration

Transbronchial needle aspiration (TBNA) is a sensitive, accurate, safe, and cost-effective technique in the diagnosis and staging of lung cancer.^{77,80-87} Also used in diagnosis of benign diseases.⁸⁸

Bronchography

Bronchography can be performed by injecting contrast material through the working channel of the flexible bronchoscope in order to delineate anatomic abnormalities.⁸⁹ The flexible instruments can be situated in the area of interest, thus less contrast material is needed. In addition, some of the contrast can be suctioned back at the end of the procedure, thus decreasing the risks of atelectasis and chemical pneumonitis.

Endoscopic Intubation

Intubation of a difficult airway may be accomplished with the aid of a flexible bronchoscope even in preterm neonates (e.g. in patients with Pierre Robin syndrome, craniofacial trauma).⁹⁰ With ultrathin instruments, intubation may be performed with endotracheal tubes as small as 2.5 mm.

Drug Application

Bronchoscopic administration of surfactant may represent an effective method of delivery in acute respiratory distress syndrome.⁹¹ Furthermore, in persistent atelectasis unresponsive to medical therapy bronchoscopic instillation of recombinant human DNAase has been found to be useful.⁹²

Closure of Bronchopleural Fistulae

FB with the delivery of methacrylate adhesive to a bronchopleural fistula may be a reasonable alternative to operative closure when the operative risk is great.⁹³ As the glue should not come into direct contact with the bronchoscope, it should be injected through a catheter placed through the working channel of the instrument.

Ultrathin Bronchoscopy

The ultrathin bronchoscope currently being studied has an outer diameter of 2.8 mm and an inner channel diameter of 1.2 mm and is made up mainly of fiberoptic bundles.

This device has been developed to overcome the low diagnostic yield of FB for small lesions less than 20 mm in

diameter.⁹⁴⁻⁹⁷ Complexities of the distal airway anatomy requires fluoroscopic or CT guidance to maneuver the scope to the peripheral lesions.

Virtual Bronchoscopy

Virtual bronchoscopy (VB) combines multidetector helical CT with computer-assisted image processing to generate high quality intra- and extraluminal views of the airways. Virtual bronchoscopy is a computer-generated, three-dimensional reconstruction technique that simulates a bronchoscopist's view of the airways.⁹⁸

It accurately shows the lumen and the diameter of the trachea, main bronchi, and the bronchial tree down to the fourth order of the bronchial orifices and branches.^{99,100}

According to a study conducted at St Mary's Hospital, London, virtual bronchoscopy is a complementary investigation to conventional bronchoscopy, especially when conventional bronchoscopy is poorly tolerated. Their meta-analysis concluded that though conventional bronchoscopy (FB and rigid bronchoscopy) are the gold standard investigations, VB is accurate in visualizing areas inaccessible to the FB especially bronchial obstructions and endoluminal lesions, and for accessing tracheobronchial tree beyond airway stenosis, bronchoesophageal fistulas, post lung transplantation anastomosis, and suspected foreign body aspiration.

However, it is not reliable in diagnosis of dynamic airway or mucosal lesions.^{101,102}

Hence in selected cases VB can assist and direct FB, but can never replace FB.¹⁰²

Limitations

- Visualization of complex bronchial branching may be complicated by partial volume effects
- Early mucosal or submucosal changes cannot be detected
- A histological tissue sample cannot be obtained, neither can any other therapeutic maneuver be performed
- Very viscous secretions or endoluminal thrombus can simulate an occlusion
- It does not detect any dynamic causes of airway obstruction (e.g. vocal cord paralysis or tracheomalacia) because it is a static technique performed at the end of inspiration
- Exposure to radiation
- It can be created from any routine chest CT on a 16 to 320 MDCT as long as raw data remains available on the scanner to allow thin reconstructions
- Obtaining good quality data to construct VB may not be possible in young infants with fast respiratory rates.

Therapeutic Bronchoscopy

Flexible bronchoscopy has expanded immensely in its therapeutic spectrum since its initial inception. Rigid bronchoscopy has become less popular. Nonetheless, rigid bronchoscopy remains an invaluable tool and should be considered for control of the compromised airway, massive

hemoptysis, silicone stent placement, and removal of large foreign bodies, especially in the pediatric age group.¹⁰³

Indications for Therapeutic Flexible Bronchoscopy

Removal of foreign body, mucus plug, blood clot

When diagnosis of foreign body aspiration is certain, the child can be directly taken up for rigid bronchoscopy under general anesthesia. However, when situation is doubtful (dictum is “Always suspect a foreign body”), FFB is preferred. Similarly, occasionally a foreign body would be found in the airways when it was not the least suspected. Most foreign bodies are left alone on FFB and managed under general anesthesia by rigid bronchoscope.⁴ However, if the foreign body is in small pieces or located in a peripheral airway suction/retrieval by baskets or ureteral forceps externally coated with Teflon, to allow frictionless passage through the narrow suction channel of the FFB, through the flexible scope may be attempted.^{104,105}

Occasionally, the attempt to remove the foreign body by the rigid scope, even in the hands of most competent and experienced bronchoscopist fails. A re-evaluation by FFB in such cases is helpful in planning the further course of management.

Sometimes, even after successful retrieval of the foreign body the clinical and radiological abnormalities do not improve well. This raises the possibility of incomplete removal. Re-evaluation by FFB may show this to be because of another piece of the foreign body or due to granulation, congestion and mucopurulent plugs.

Contraindications: Lack of experience and lack of availability of all necessary endobronchial accessories are the more important contraindications. Removal of a foreign body using FB should be attempted only by or under the supervision of an expert bronchologist.

Procedure: Foreign body removal using FB is carried out in stages:

- Dislodging the foreign body
- Grasping or securing the object
- Removing it along with the flexible bronchoscope as single unit.

A balloon catheter is usually used to dislodge the foreign body from the distal airways and to pull it into the proximal airways. Once the object is grasped and secured with an appropriate accessory, it is kept very close to the tip of the flexible bronchoscope to reduce danger of losing it in the subglottic area or at the level of vocal cords.

A variety of ancillary accessories (forceps, grasping claws, snares, baskets [dormia, fishnet], and magnets) are available for foreign body extraction.¹⁰³ Once the object is in the trachea, the patient can also be asked to cough to expel the foreign body. Lasers and cryoprobes can also be used if a significant amount of granulation tissue is present.

A cryoprobe passed through the flexible bronchoscope can be used to retrieve the foreign body by placing the tip in contact with the object until the point of contact is frozen, leading to adhesion (cryoadhesion). This allows for en bloc removal of the object with the cryoprobe and the flexible bronchoscope.

This approach is especially useful for the removal of blood clots, mucus plugs, friable organic material, and small inorganic objects. Occasionally, laser instruments can assist in the removal of large objects by breaking them up into smaller pieces. Self-expanding metallic stents embedded in the bronchial mucosa can be extracted by fracturing the wires using laser energy.¹⁰³

Complications during foreign body removal:

- Central airway obstruction
- Airway wall perforation
- Flooding of the airways with secretions or blood.
- Hypoxia, bronchospasm, arrhythmias,
- Laryngeal edema
- Bacteremia, fever
- Migration of the object to distal airways
- Object fragmentation
- Loss of the object at the glottis during removal efforts.

The key for the success in foreign body removal is airway protection, an experienced operator, adequate equipment, and availability of a rigid bronchoscope for an emergent situation.¹ There are some drawbacks of the latter technique compared to rigid bronchoscopy:

- The procedure is more time-consuming,
- The inability to perform mechanical resection may result in incomplete resolution of the obstruction and may necessitate more laser energy to vaporise the lesions,
- Complications such as bleeding are difficult to control,
- Flexible endoscopes are easily damaged.

Bronchoalveolar lavage for pulmonary alveolar proteinosis

Aspiration of cysts: mediastinal or bronchogenic

Drainage of lung abscess

Hemoptysis

Pulmonary toilet

Difficult endotracheal intubation

Endoscopy-Assisted Tracheal Intubation and (Selective) Bronchial Intubation—Direct visualization of the airway via a flexible bronchoscope has been reported to be of assistance in the intubation of the patient with a difficult airway and during placement of a bronchial blocker to enable single-lung ventilation during video-assisted thoracoscopic surgery.¹⁰⁴

Percutaneous dilational tracheostomy

Pneumothorax/bronchopleural fistula (fibrin glue therapy)

Gene therapy

Dilation of stricture and stenosis: balloon bronchoplasty

Stent placement

Stents: Stents are devices used for the internal splinting of luminal structures¹⁰⁵ for counteracting extrinsic compression from tumors or lymph nodes. They have been very rarely used in children.

Intralesional injection: *cidofovir, mitomycin, steroid*

Bronchial thermoplasty

Recently, Cox and associates^{106,107} reported their experience with bronchial thermoplasty in asthmatic adults. This novel technique involves treatment of airways with a specially designed, four-wired, thermoplasty probe that ablates airway smooth muscle.

The thermal effect appears to remain confined to the airway wall and the immediate peribronchial area without associated fibrosis. The procedure seems to be well tolerated and patients demonstrate an improvement in airway hyper-responsiveness, quality of life and symptom-free days, and peak flow measurements. However, the technique has not been tried in children.

COMPLICATIONS OF FLEXIBLE BRONCHOSCOPY

FFB is a safe procedure even in the very sick, ventilator dependent children with major complications being uncommon^{17,22,34} and deaths rare (one death having been reported in 1987 by Wagener).¹⁰⁸ Complications in three of the series are listed in Table 11.

Transient dip in arterial oxygen saturation, mild nasal bleed, transient hemoptysis, transient stridor, increased cough for a short while, over-sedation are some of the relatively common complications encountered. All the

possible complications are listed in Table 12. It is important to anticipate problems, monitor the patient closely and take adequate precautions to minimize complications.

Recently, Bar-Zohar and Sivan have reported their experience with FFB in severely sick children in the PICU.⁵² In 155 procedures, no procedure-related death was encountered. Nor did they encounter any significant nasal/airway trauma, stridor, hemoptysis, pneumothorax, septicemia or cardiac arrhythmias. There was no significant reduction in PaO₂/FiO₂ ratio or deleterious effect on blood pH or PaCO₂.

RECOVERY AND POSTPROCEDURE CARE

On completion of the procedure, the child should be awakened whilst still fully monitored. Monitoring of oxygen saturation should continue during the recovery period. An intravenous line should be left *in situ* until the child is fully awake and tolerating oral fluids. Late complications are rare, but have been described, including progressive stridor necessitating intubation.¹⁰⁹ The sedated child should never be left unobserved and may require the same formal recovery facilities as after a general anesthetic.

The child should remain in the recovery area until cardiovascular and respiratory stability are assured and the patient is awake and orientated.

If local anesthetic agents have been applied to the airway then laryngeal reflexes may be depressed for up to an hour after the procedure. Children should not eat or drink during this period as the risk of aspiration may be increased.⁴

Table 11: Complications of FFB^{17,22,34}

	Wood (n = 1095)	GRH (n = 3226)	Reddy and Vauthy (n = over 4000)
<i>Major</i>			
Pneumothorax	2	0	6
Lung abscess	1	0	0
Laryngospasm	1	8	0
Massive hemorrhage			
Prolong hypoxemia requiring intubation	0	3	0
Hypoxemia requiring oxygen/admission	0	6	0
Arrhythmias	nil	nil	nil
<i>Minor</i>			
Minimal nasal bleeding	8	28	5
Mild hemoptysis	0	0	0
Increased cough for up to 1-2 hrs	0	47	0
Transient stridor	2	47	1
Transient O ₂ desaturation		150	
Over-sedation/anesthetic Complication	5	0	
Transient bradycardia	13	34	several

Table 12: Possible complications (all of them are uncommon)^{17,22,34}

Physiological	Hypoxia, hypercapnea, arrhythmias, laryngospasm, bronchospasm
Bacteriological	Transient fever, iatrogenic infection (if standard sterilization techniques not followed), bacterial endocarditis in congenital heart disease patient, cross infection. Bronchoscopist and assistants exposed to patient's infection
Mechanical	Pneumothorax, hemoptysis, epistaxis, laryngeal, trauma, mucosal edema, subglottic edema
Anesthetic complications	Over sedation, apnea

CONTRAINDICATIONS TO BRONCHOSCOPY

FFB should not be performed in the absence of a suitable indication or appropriate equipment and personnel skilled in its use. There are no absolute contraindications. Relative contraindications are those which increase the risk of the procedure. Cardiovascular instability, pulmonary arterial hypertension, bleeding diathesis, severe bronchospasm, hypoxemia are some examples where bronchoscopy is relatively contraindicated.^{3,4,18}

ETHICAL ASPECTS OF BRONCHOSCOPY

Bronchoscopy is unethical in a clinical context unless performed with the maximum attention to safety, and in a context in which the potential benefit to the child justifies the perceived risk of the examination. Fully informed consent, in accord with local and national guidelines, is mandatory.

The ethics of research bronchoscopy have recently been debated.¹¹⁰⁻¹¹² In general, the performance of a bronchoscopy cannot be considered to be of such low risk that it is justified to perform it on a child for research purposes alone.¹¹³

However, if a clinically indicated bronchoscopy is performed, then it is fully justifiable to use clinically gathered material (e.g. BAL fluid, endobronchial biopsy material) for research purposes, provided informed consent has been obtained from the family and age-appropriate assent from the child.¹¹⁴ It may also be legitimate to prolong the procedure for a short time to make extra measurements, for example endobronchial pH.¹¹⁵

RISK/BENEFIT RATIO

The risks involved are minimal except in critically ill child whose hemodynamics are unstable. To keep the risks low oxygenation is continued throughout the procedure. If still the child tends to desaturate the bronchoscope is removed immediately and reinserted again after the child

stabilizes. Care at minor details during the procedure ensures that the mucosa of the nostril, pharynx and lower airways are traumatized the least. Keeping a complete control over the angle of the tip of the bronchoscope and avoiding suctioning when the scope is against the wall is further helpful. Another precaution to minimize suction trauma is to keep the negative suction pressure in the recommended range. Similar precautions are necessary during BAL. Complications encountered during BAL by some workers are summarized in Table 11. When inserting the scope into glottis a careful control over the tip of the scope and adequate local anesthesia of the area allows the skilled bronchoscopist to maneuver the scope into the trachea smoothly. This is helpful in avoiding post bronchoscopy stridor/ laryngeal spasm. The benefits that will accrue to the patient by bronchoscopy should be evaluated carefully before the procedure is undertaken. Since FFB in skilled hands is safe and tolerated well most experts believe that it is an underused procedure and should be undertaken in any puzzling/difficult pulmonary condition.

FLEXIBLE VERSUS RIGID BRONCHOSCOPY

The question now is "Has flexible bronchoscope completely replaced the rigid one?" Most experts agree that the two are complementary with each having its advantages and limitations (Table 13). Overall, for majority of cases FFB is the procedure of choice for diagnosis while rigid bronchoscopy is the procedure of choice for therapeutic indications like removal of foreign body. In general, if a particular function can be performed by either of the two scopes, the flexible one would be preferred by most as FFB has lesser complication rate, improved vision, small size and does not require anesthesia. Most neonatologists, intensivists and pulmonologists in advanced medical centers of the world have now acquired the skills to perform this procedure in their units.

Special Indications of Rigid Bronchoscopy

- Foreign body removal
- Endobronchial procedures
- Evaluation of bronchoesophageal cleft
- Examination of anterior commissure of larynx
- Massive hemoptysis
- Dilatation of stenotic airways.

FUTURE OF PEDIATRIC FFB

Over the past 2 decades applications of pediatric FFB have widened greatly. More and more specialists, pulmonologists, neonatologists, anesthesiologists, ENT surgeons, cardiothoracic surgeons and pediatric surgeons have acquired the skills and the equipment to use this instrument for the benefit of their patients. As subspecialties advance and PICUs and NICUs reach higher levels of sophistication

Table 13: Comparison of rigid and flexible bronchoscopy

	<i>Rigid</i>	<i>Flexible</i>
1. Anesthesia	General	Local + sedation
2. Operation theater	Required	Not required Done in bronchoscopy suite/PICU/NICU/Bedside
3. Nose and nasopharynx	Not seen	Evaluated
4. Upper lobes	Not entered	Entered
5. Distal airway	Not evaluated	Evaluated
6. Beyond a stenosis	Cannot pass	May pass
7. Dynamics of airways	Not visualized	Visualized well
8. Bronchoalveolar lavage (BAL)	Not possible	Ideal
9. Through endotracheal tube	Cannot pass	Can pass
10. Simultaneous ventilator	Cannot work	Can work
11. OPD procedure	No	Can be
12. Aid to difficult endotracheal intubation	No	Yes
13. Aid to extubation	No	Yes
14. Tracheostomy evaluation	Limited value	Valuable
15. In small infants	Possible	Easy
16. In prematures	Not possible	Possible
17. Selective bronchogram	Not possible	Possible
18. Selective bronchial intubation	Not possible	Possible
19. Working channel	Large	Small

in the developing countries FFB will be done more commonly here too.

Newer applications of FFB in both diagnosis as well as in therapy are being explored. The BAL fluid can be analyzed by the sensitive techniques of polymerase chain reaction (PCR) and ELISA to detect organisms like *Mycobacterium*, *Pneumocystis*, CMV, HIV, etc. Delivery of drugs to the targeted parts of lung and airways can be achieved by FFB, especially if the 'drug' cannot be well nebulized. Gene therapy for cystic fibrosis may be possible soon and FFB may be one method by which the gene can be delivered to the respiratory epithelium.⁴¹

A study¹¹⁶ has described a method of quantitatively assessing the degree of airway collapse in infants and children with tracheobronchomalacia. A computer-assisted method is described besides the manual method. This combination of FFB with the computers's help may prove synergistic in future.

Persistent and Recurrent Pneumonia in Children

Varinder Singh, Rajesh Kumar Meena

INTRODUCTION

Pneumonia is clinically defined as combination of respiratory symptoms (cough, dyspnea or tachypnea) and signs (fever, crepitations, focally-reduced breath sounds, fremitus or wheeze).

Persistent or nonresolving pneumonia is defined as the persistence of symptoms and radiographic abnormalities in a child with lower respiratory tract infections for more than a month despite a course of adequate antibiotic therapy.¹ Documentation of nonresolving abnormal radiographic findings is important for defining a case of persistent pneumonia. Recurrent pneumonia is defined as at least two distinct episodes of radiologically established pneumonia within the same year or three or more such episodes over any time period.² For the diagnosis of recurrent pneumonia, there must be documented complete resolution of clinical and radiological findings between acute episodes. Often distinguishing recurrent and persistent pneumonia is difficult as all the relevant radiographs, particularly those taken after the child gets better, may not be available. As many features of the two might be overlapping both are usually considered together.

ETIOLOGY AND PATHOGENESIS

The presence of abnormal radiographic findings is important for defining an episode of pneumonia in a case of persistent pneumonia. Though radiological lung infiltrates due to acute pneumonia usually resolves within 2 to 4 weeks but a substantial number of children fails to completely clear infiltrates within a period of 4 weeks. The rate of resolution of the radiological shadows depends on the causative agent. Infiltrates caused by common viral agents like respiratory syncytial virus and parainfluenza usually take 2 to 3 weeks to clear while those associated with pneumococcal pneumonia can take up to 6 to 8 weeks and

those associated with adenoviral disease up to 12 months.³ Beside infections, the persistent lung infiltrates can also occur due to a variety of non-infective causes as well.

For the better understanding of the etiology and pathogenesis, the patients with persistent pneumonias are further divided into those who have a single segment/lobe involvement and those in which multiple lobes are involved. Infiltrates that recur in a single lobe or segment of the lung are more likely to be caused by localized pathology like local airway obstruction—intra/extraluminal, structural abnormalities of airway or lung parenchyma. On the other hand, multilobar involvement may be more often a result of a systemic problem. Persistent pneumonias can result from deficiencies in the local pulmonary or systemic host defences or from underlying disorders that modify lung defences. But, majority of children with persistent or recurrent (PRP) have no defect in host defence while few of these children may have transient alteration in their host defences.

Unilobar Persistent Pneumonia

Localized airway narrowing, due either to an intraluminal or an extraluminal compression leads to retained secretions in the area distal to the obstruction. Impaired mucociliary clearance in the involved leads to accumulation of secretions distal to obstruction, in which infection supervenes.

Various causes of unilobar persistent pneumonia are described in Table 1.

Foreign body aspiration the most frequently leads to intraluminal obstruction in children age 6 months to 3 years. Commonly, foreign bodies impact in the right bronchus because it takes off at a less acute angle from the trachea than the left bronchus. Food or vegetable items such as peanut, gram seed, cashew, etc. are commonly aspirated. It is important to obtain a detailed history of any choking and coughing episodes, but the physician should

maintain a high index of suspicion for foreign body aspiration even in the absence of such history as the choking event may go unnoticed by the care giver. Symptoms are very variable. While in many cases there is a definite history of

choking while eating or playing or mouthing small objects. This is followed by onset of cough and breathlessness instantly or after a variable interval of minutes to hours. Common symptoms include noisy breathing or wheeze, cough, dyspnea, and occasionally hemoptysis. Initial signs of foreign body aspiration include localized wheezing and asymmetry of breath sounds, which are decreased on the side of aspiration.⁴ Sometimes the aspiration episodes are not observed when they occur, and respiratory symptoms may not manifest immediately afterward. As a result, some children are treated for pneumonia and “recover,” only to present later with recurring symptoms. Many a ‘forgotten’ foreign bodies are detected later when the child develops and gets investigated for chronic suppurative lung disease like atelectobronchiectasis. Chest skiagram will often show localized hyperinflation or segmental/lobar collapse. However, in many small children the foreign body may remain in trachea due to its large size and the skiagram may be absolutely normal. Persistent tracheal noises or wheeze on auscultation, particularly when the child is quiet may suggest a tracheal foreign body.

Usual organisms with multidrug resistance to commonly used drugs or unusual organisms can also lead to a non-resolving pneumonia in an immunocompetent as well as an immune-deficient host. Parasites like *Echinococcus* can lead to pulmonary hydatidosis along with liver and kidney involvement (Figs 1A to D).

Table 1: Common causes of unilobar persistent pneumonia	
Intraluminal obstruction	<ul style="list-style-type: none">• Foreign body• Endobronchial granuloma—tuberculoma• Bronchial tumor—hemangioma, lipoma, adenoma, carcinoid, papilloma, etc.
Extraluminal compression	<ul style="list-style-type: none">• Lymphadenopathy:<ul style="list-style-type: none">– Infectious (Tuberculosis)– Noninfectious (Malignancy-Hodgkin’s, sarcoidosis)• Vascular rings and slings• Esophageal foreign body• Cardiomegaly• Inflammatory pseudotumor
Structural abnormalities	<ul style="list-style-type: none">• Congenital anomalies<ul style="list-style-type: none">– Bronchial stenosis– Tracheal bronchus– Congenital cystic adenomatoid malformation– Congenital lobar emphysema– Bronchogenic cyst– Pulmonary sequestration• Right middle lobe syndrome• Bronchiectasis

Figs 1A to D: Hydatid disease of lung (A) Multiple round opacities in right upper and left lower lobe areas (small arrow). Opacity in the left lung field shows cavitation; (B) CT chest showing pneumonic patch around the infected cyst (big arrow); (C and D) and abdomen showing multiple nonenhancing cystic hypodense lesions in liver and spleen hydatid (curved arrows)

Children with active tuberculosis may also present with persistent focal infiltrates or atelectasis caused by endobronchial granulations. Infectious lymphadenopathy is the most common cause of extraluminal compression, leading to chronic or recurrent focal pulmonary disease. Infectious lymph nodes causing airway compression are most commonly caused by infection with *M. tuberculosis*. In active pulmonary tuberculosis, enlarged lymph nodes occur in the perihilar, carinal, and peribronchial regions (Figs 2A to D).

Chronic bacterial infection in cystic fibrosis can lead to lymphadenopathy, pertussis presents with lymphadenopathy in 35 percent of cases. Other less common bacterial causes of lymphadenopathy include—brucellosis, tularemia, and *Mycoplasma* infection (in 34 percent of pediatric cases). However, in most of these situation compression of the airways is not seen.⁵ Tumors are a rare cause of intraluminal obstruction in children but should not be overlooked as a reason for recurrent localized pneumonia. Tumors such as lymphoma, plasma cell granulomas and histiocytomas can also cause extraluminal airway compression. Inflammatory pseudotumors are the most common benign primary pulmonary growths in children. Most patients have no symptoms; those who have, manifestations include fever, cough, chest pain, and recurrent pneumonia.

Congenital anomalies of the heart and great vessels may also cause extrinsic obstruction of the large airways. Children with significant left to right shunt also are more

prone to repeated LRTIs but in that situation the lung involvement is multi focal and bilateral. Vascular rings and slings and esophageal foreign bodies are other causes of extraluminal compression causing unilobar obstruction. Such children more often present with feeding difficulty, noisy breathing and/or stridor.

Right middle-lobe syndrome is the most common recurrent focal finding encountered in clinical practice. It is the atelectasis of the right middle lobe persisting for more than one month or recurring twice or more despite treatment,⁶ a susceptibility attributed to anatomic and physiologic causes. Right middle-lobe syndrome is seen most often in children with asthma. Tuberculosis remains the most common infectious etiology of right middle lobe syndrome. Similarly, the positioning of the right upper lobe bronchus in small infants makes them more prone to collapse of the upper lobe with most LRTIs. This collapse may resolve by chest physiotherapy but can occasionally persist for long times.

Structural abnormalities—either congenital or acquired, can lead to recurrent LRTI. These abnormalities include tracheal bronchus, bronchiectasis, bronchial stenosis, and bronchomalacia. Other congenital anomalies of foregut development, such as congenital cystic adenomatoid malformation (CCAM), congenital lobar emphysema (CLE), bronchogenic cyst, and pulmonary sequestration, can also lead to recurrent pneumonia.⁷ CCAM's represent about 25

Figs 2A to D: Persistent pneumonia due to TB: (A) Consolidation of right lower lobe; (B) Compressed right side lower lobe bronchus; (C and D) Large necrotic mass of lymph nodes (curved arrows) compressing airways

percent of congenital lung abnormalities. Most cases are diagnosed by prenatal ultrasonography or present shortly after birth as respiratory distress. A small number of these present later associated with recurrent pneumonia caused by bronchial compression. However, it must be said that while the congenital anomalies can lead to pneumonia, both recurrently or persistently, but more often these anomalies are unmasked due to a skiagram done for intercurrent respiratory symptoms to which they may not actually be causally related.

Illustrative Case 1

R, a 5-month-old male, presented with cough for 10 days and fever, fast breathing and difficulty in feeding for 3 days. On examination, there was tachypnea with decreased air entry on right side. The baby had been admitted and treated as right side consolidation about 3-4 weeks back in another hospital. He was discharged when he started feeding and respiratory rate improved. His chest X-ray shows collapsed right lung with hyperinflation of left lung, on detailed history and evaluation, it became evident that in both the episodes child had fever, cough and rapid breathing. The treating pediatrician admitted the patient after the chest skiagram showed significant

shadows. In view of the completely opaque right hemithorax a fiberoptic flexible bronchoscopy was done. It showed inflamed trachea which had a small branch on right side that too tapered off suddenly and was not negotiable further by the bronchoscope. His BAL also showed significant growth of *Acinetobacter* and *Klebsiella* sp., and the patient improved symptomatically with specific therapy though the radiological shadow persisted. CECT chest showed complete lack of pneumatization of right lung with fluid filled nondilated poorly dividing bronchial tree within the non-aerated parenchyma, with significant right sided mediastinal shift and herniation of left lung towards the right side. Proximal part of right main bronchus is aerated but distal part shows smooth tapering with nonvisualization of distal bronchus. Right pulmonary artery was also smaller in size. These findings were suggestive of hypoplasia of right lung.⁸ In this case an intercurrent chest infection unmasked the presence of the underlying lung anomaly to which it was not causally related (Figs 3A to D).

Multilobar Persistent Pneumonia

Pneumonia that occurs in multiple locations or affects more than one lobe indicates a disease process which is more generalized, that a systemic consideration must be taken for

Figs 3A to D: Hypoplasia of right lung: (A) Complete opacification of right hemithorax with hyperinflated left lung cross herniating to the right side with mediastinal shift; (B) Stump like ending of the right main bronchus; (C) Lack of any bronchial tree in the homogeneous hypoplastic right lung; (D) Hypoplastic right pulmonary artery (arrow)

evaluation. Various causes of childhood multilobar persistent/recurrent pneumonia are described in Table 2.

Aspiration is the most common cause of recurrent multifocal pneumonia in children. The location of radiographic infiltrates depends on the position the child was in when aspiration occurred.⁹

Aspiration syndromes can be divided into:

- a. Aspiration from above can occur in cases with impaired swallowing due to central nervous system (CNS)

Table 2: Enumerates some of the common causes of multilobar persistent/recurrent pneumonia

- Aspiration syndromes
 - From above—impaired swallowing
 - CNS or neuromuscular disorders
 - Anatomic abnormalities like cleft palate, laryngeal cleft, etc.
 - Esophageal obstruction or dysmotility
 - Forceful feeding
 - From below—regurgitation
 - Tracheoesophageal fistula (TEF)
 - Gastroesophageal reflux (GER)
- Infections
 - Drug resistant organisms or unusual organisms
 - Fungal pneumonia
 - PCP pneumonia
 - Hydatidosis
- Asthma
- Allergic bronchopulmonary aspergillosis
- Structural abnormalities
 - Tracheobronchomegaly,
 - Cartilage deficiency/incomplete cartilage ,
 - Segmental bronchomalacia
- Congenital heart disease
 - Left to right shunt, e.g. ventricular septal defect, atrial septal defect, patent ductus arteriosus
- Defence mechanism aberrations
 - Cystic fibrosis
 - Primary ciliary dyskinesia
- Immune deficiency disorders
 - Primary: Antibody deficiency, cell-mediated immune deficiency, complement deficiency, phagocytic defect
 - Secondary:
 - HIV
 - Iatrogenic (steroids, immunosuppressive drugs, postradiotherapy, etc.)
 - Malignancy (leukemia and lymphoma, etc.)
- Others
 - Interstitial or diffuse lung disease
 - Pulmonary hemosiderosis (PH)
 - Hypersensitivity pneumonitis (HP)
 - Alpha1-antitrypsin deficiency
 - Pulmonary alveolar proteinosis (PAP)
 - Bronchopulmonary dysplasia

disorders, neuromuscular diseases, structural abnormalities of the oropharynx, forceful feeding, esophageal obstruction—whether extrinsic (vascular rings or mediastinal masses) or intrinsic (foreign bodies or strictures). Esophageal dysmotility caused by achalasia can also lead to repeated aspiration.

Typically, in all these situations there is history of feeding difficulty with cough during feeding due to aspiration, choking like episodes along with recurrent regurgitations and difficulty in weight gain. On examination, child can have tachypnea along with wheeze and or crepts in dependent areas.

- b. Aspiration from below usually occurs in cases with tracheoesophageal fistula and gastroesophageal reflux. Most forms of TEF are diagnosed in the neonatal period, but small, H-type fistulae may not present until later in childhood, when chronic aspiration through the persistent abnormal communication leads to recurrent lower respiratory tract infection. Typically, such children have choking or coughing while drinking liquids though they may be able to accept semi-solids without any symptoms.

Gastroesophageal reflux disease (GERD) can lead to respiratory symptoms due to several mechanisms including repeated aspirations and recurrent pneumonia. Mechanisms which are involved in the respiratory diseases are by direct effect of aspiration leading to tracheitis, bronchitis, pneumonia, atelectasis, or indirectly by provoking airway hyperreactivity in response to inflammation.

There are several methods of studying GER and these include: 24 hours pH monitoring; Gastrointestinal Scintiscan (shows both acid and non-acid reflux, also can detect the pulmonary aspiration of gastric material) and Esophagoscopy (detects esophagitis confirmed by biopsy). Upper GI barium studies are usually not useful though are more sensitive for demonstration of anatomical abnormalities like hiatus hernia along with esophageal motility.

Illustrative Case 2

Patient A, a 2-year-old male presented with complaints of cough and fever for 15 days on presentation with past history of recurrent similar episodes of cough. The cough was more after meals. There were associated complaints of decreased appetite and not gaining height and weight. He had been admitted to hospital 7 times in past since the age of 2 months for treatment of an episode of pneumonia. He had history of regurgitation of feeds in neonatal period which now had decreased. On examination, his breathing was fast. His height and weight both was less than 3rd percentile. Chest examination was unremarkable except for the presence of mild distress and bilateral crackles. The chest skiagram showed bilateral basal pneumonia in lower lobes. In view of the past history of regurgitations and history of cough related to feeds, the

child was investigated for GER. On GER scintiscan there was evidence of significant reflux into the upper part of the esophagus. No tracers were seen in the bronchial tree but microaspiration could not be ruled out. The patient was treated with antireflux therapy and showed a good response in the form of no vomiting, improved appetite and improved respiratory symptoms (Figs 4A and B).

Asthma is the most common cause of recurrent/persistent infiltrate and is often misdiagnosed as recurrent or persistent pneumonia. The pathophysiology of this condition includes mucous plugging and edema of peripheral airways. Such cases can have streaky shadows or small areas of atelectasis appearing as inhomogeneous infiltrates. Collapse of the right middle lobe due to plugging in children with asthma has been well described.

Another set of patients who have recurrent chest infiltrates and respiratory symptoms are those who have allergic bronchopulmonary aspergillosis (ABPA). ABPA is suspected in children with asthma of any severity or children with cystic fibrosis (CF) who have recurrent pulmonary infiltrates, peripheral eosinophilia, and an elevated total serum IgE. A negative immediate-type skin test excludes ABPA, but the diagnosis can be established only by careful serologic studies.

In disorders of the mucociliary system, natural clearance of the airway is compromised. The physician must not overlook disorders such as CF and primary ciliary dyskinesia (PCD) as causes of recurrent lower respiratory infection. Cystic fibrosis is an inherited autosomal recessive disorder recognized by a classic triad of chronic pulmonary disease, pancreatic insufficiency, and elevated sweat chloride concentration. In cystic fibrosis, the inflammatory response initially manifests as chronic bronchiolitis and bronchitis but, ultimately, causes structural changes in the airways and produces bronchiolectasis and bronchiectasis. Sweat chloride estimation is done for establishing the diagnosis of cystic fibrosis. Recurrent pneumonia with chronic sinusitis, steatorrhea, or failure to thrive forms an indication for doing sweat chloride test.

Primary ciliary dyskinesia, another autosomal recessive disorder, is caused by ultrastructural defects in the cilia or abnormal organization of microtubules within each cilium. A child with recurrent pneumonia, chronic otitis media, or sinusitis must be evaluated for PCD, once other diagnoses such as CF and immunodeficiency, have been excluded.

Children with congenital heart disease are predisposed to recurrent pneumonia for various reasons. Those with left to right shunt get repeated infections due to pulmonary congestion while in others an enlarged cardiac chamber and/or pulmonary arteries can cause extrinsic compression of the airway, impairing its drainage. Echocardiography helps to rule out the heart diseases, like congenital heart lesions, vascular slings, abnormally dilated heart chambers, etc. which can lead to persistent or recurrent pneumonias.

Children with BPD have risk factors that predispose them to recurrent pneumonia. These include feeding difficulties that make them susceptible to aspiration, an increased incidence of bronchomalacia, impaired airway clearance mechanisms, focal airway strictures, and a high incidence of GERD.

Interstitial or diffuse lung disease is not uncommonly misdiagnosed and treated as persistent pneumonia. Typically these cases do not have significant fever but otherwise have a relentlessly progressive breathlessness with persistent lung shadows.

Illustrative Case 3

Eight-year-old female, A, presented with mildly productive cough and breathing difficulty of 2 months duration. On examination, she had tachypnea and bilateral crepts along with grade 4 clubbing. CBC was unremarkable. Her chest X-ray showed infiltrates in bilateral lung fields with areas of breakdown. Her CECT chest shows interstitial septal thickening with associated ground-glass opacity and traction bronchiectasis in bilateral lungs. Her lung biopsy was done and was reported as non-specific interstitial pneumonitis (Figs 5A and B).

Figs 4A and B: Persistent pneumonia due to gastroesophageal reflux disease: (A) Patchy pneumonia in right lung predominantly in the paravertebral gutter-dependent area for a young child; (B) GER scintiscan showing reflux up to middle of esophagus

Figs 5A and B: Interstitial lung disease: (A) Inhomogeneous opacities in both lung fields with small fibrotic right lung; (B) CT chest showing areas of ground-glass shadowing with fibrosis and development of traction bronchiectasis (arrow)

The primary or secondary immunodeficiency disorders can also lead to recurrent multilobar pneumonia. The primary immunodeficiency diseases, relatively rare disorders may be characterized by severe clinical expression early in life. Primary immunodeficiencies include disorders of antibody, cell-mediated immunity, complement, and phagocytosis. Children with an antibody deficiency present with recurrent sino-pulmonary infections as well as infections outside the respiratory system due to encapsulated bacteria and enteroviruses.¹⁰

Individuals with defects in cell-mediated immunity, such as severe combined immunodeficiency (SCID), DiGeorge syndrome, and Wiskott-Aldrich syndrome (WAS), may have difficulty with recurrent pneumonia due to pyogenic bacteria, *Pneumocystis jiroveci*, and viruses. Patients with complement deficiencies most often present with bacteremia, septic arthritis, and meningitis caused by encapsulated bacteria. Phagocytic disorders such as chronic granulomatous disease (CGD) are characterized by infections of the skin, reticuloendothelial system, and respiratory tract caused by catalase-positive bacteria or fungus. Recurrent pneumonia involving different locations with a residual shadow or incomplete clearance is a hallmark of this disorder of phagocytosis.

Secondary immunodeficiency caused by chemotherapy, steroid therapy, sickle cell disease, diabetes, or human immunodeficiency virus may also presents as recurrent diffuse pneumonia. Risk factors for HIV must be assessed in a child with other recurrent infections, because respiratory infections such as *Pneumocystis jiroveci*

pneumonia are common in acquired immunodeficiency syndrome.¹

EPIDEMIOLOGY

As the etiological agents and causes vary in different regions of the world depending on the industrial development and geographical location, thus the causes and incidence of persistent pneumonia vary in different countries. Although the precise prevalence is not well established but, results of various studies are shown in Table 3.

CLINICAL PRESENTATION

Mostly the parents bring their ward with complaints which are specific for respiratory system like—cough, dyspnea, chest pain and constitutional symptoms like—fever, weight loss, fatigue/malaise, poor appetite; where according to them the condition is persisting for a long time. Presence of persistent fever, limitation of activity, persistent tachypnea and labored breathing, chronic sputum production, digital clubbing, failure to thrive, signs of severe hypoxemia, positive family history—indicates serious lower respiratory tract infection.

APPROACH TO A CASE OF PERSISTENT PNEUMONIA

It includes detailed clinical history and examination. Detailed history includes information regarding the age of onset, frequency, duration and severity of symptoms along with neonatal course, subsequent hospitalizations and

operations. History regarding feeding problems, immunization status, any history suggestive of foreign body aspiration and allergy/atopy; along with this family history of hereditary disorder, allergy/atopy and environmental history is also important. Physical examination includes vitals, detailed anthropometry along with changes in skin and extremities (cyanosis, clubbing, rashes), any signs of pyogenic infections, presence of conjunctivitis, ENT examination, respiratory system examination, cardiovascular system for congenital heart disease, dextrocardia (assoc. with immotile cilia syndrome), nervous system—for swallowing difficulties and neuromuscular diseases, and abdominal examination.

INVESTIGATIONS

These are divided into routine (forms the basic investigations for almost all cases) and advance (done on as indicated basis).

Routine Investigations

These are done as baseline work up in a case of persistent pneumonia, before deciding the specific investigation which helps in final diagnosis and treatment. These include:

1. *Complete hemogram*: A complete blood count is used to assess anemia or polycythemia, abnormal numbers, differential makeup of leukocytes and thrombocytopenia (associated with immunological disorders such as Wiskott-Aldrich syndrome (characterized by recurrent infections and autoimmune disorders), primary hematologic cytopenia's like in aplastic anemia leading to secondary infections or suppression by disseminated virus infection). It also includes absolute eosinophil count (AEC), erythrocyte sedimentation rate (ESR), which are helpful in certain diagnosis like asthma, allergic disorders and tuberculosis, etc. Eosinophilia is

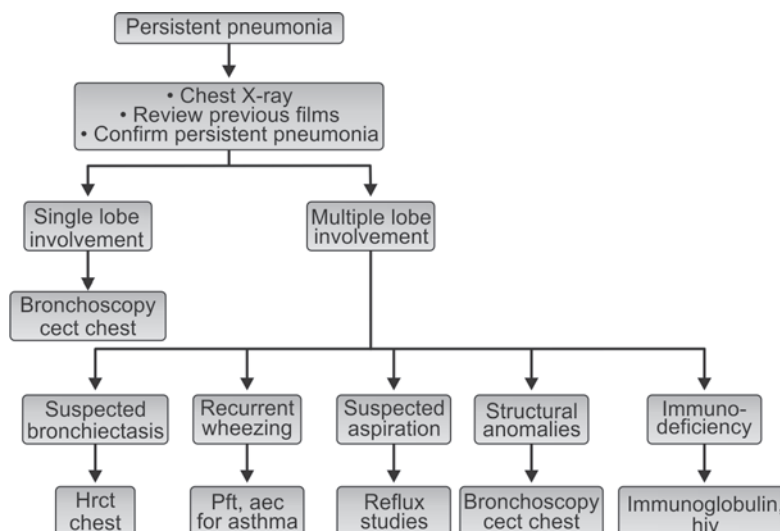

present when absolute eosinophil count (AEC) exceeds $0.4 \times 10^9/L$ and is seen in ABPA, eosinophilic pneumonias, asthma, collagen disorders, etc.

2. *Chest X-ray*: Skiagram of the chest not only forms an important basis of diagnosis and classification of infiltrates while defining disease but also helps in confirming the diagnosis, area involved, suggesting etiology and facilitates follow-up. Often such cases come with several investigations including skiagrams. These films should be arranged in serial order, to decide whether the disease is recurrent or persistent; unilobar or multilobar. Further work-up is planned to make correct diagnosis.
3. Tests for TB including tuberculin skin test and gastric aspirates for acid fast bacilli are commonly used in children with persistent or non-resolving pneumonia who are suspected of tuberculosis.

Special Investigations

The approach of unilobar or multilobar division of persistent/recurrent pneumonia helps in deciding the investigation to be chosen for the diagnosis and then treating the patient as shown in Flow chart 1. In the patients with single lobe involvement, the first in the diagnostic workup is bronchoscopy, as this allows diagnosis- like intraluminal obstructive lesions (bronchial adenoma, lipoma) foreign body, tracheal bronchus, etc. It also provides sample for microbiological investigation for any a resistant bug or unusual organism. This also helps in therapeutic intervention in cases of foreign body aspiration. If bronchoscopy is normal or inconclusive, CECT chest is another investigation which is useful in such situations as it can help find extrabronchial obstruction, bronchiectasis, distal intraluminal obstructions, structural lesions like- sequestrations, CCAM (Figs 6A to D).

Flow chart 1: Diagnostic tests for investigating persistent pneumonia

Figs 6A to D: Sequestration of lung: (A and B) Persistent cystic lesion in left lower lobe with air-fluid level, (C and D) CECT chest confirms a multicystic lesion with systemic blood supply (not seen here) and confirmed on excision

In cases involving multiple lobes and different lobes at different times, a more generalized disease should be suspected- like aspirations due to gastroesophageal reflux, asthma, immunodeficiency, cystic fibrosis, etc. and investigations for them should be planned. Lung biopsy helps in confirming the diagnosis and starting specific therapy in certain diffuse lung diseases like interstitial lung disease, cryptogenic fibrosis, hemosiderosis, etc.

CONCLUSION

Persistent pneumonia though uncommon, can be very distressing both for the patient and the pediatrician. It needs a very detailed work up using a range of investigations of which CECT and bronchoscopy appear to be the mainstay followed by investigations for aspiration. There is an array of investigations available, of which only few may be needed for an individual case. The choice of investigation is predicted by the clinical history, signs, type of radiological shadow, involvement of single/multiple lobes, etc. This can sometimes be very frustrating as no specific diagnosis may be reached in some of the patients.

ACUTE SINUSITIS**Abstract**

Sinusitis is a common illness of adolescents and childhood with significant acute and chronic morbidity as well as the potential for serious complications. Therefore, understanding is necessary for the following reason:

- For the efficacy of various antibiotics in children
- For the efficacy of various ancillary, nonantibiotic regimens
- The diagnostic accuracy and concordance of clinical symptoms, radiography (and other imaging methods) and sinus aspirations.

It is recommended that the diagnosis of acute bacterial sinusitis be based on clinical criteria in children 6 years of age who present with upper respiratory symptoms that are either persistent or severe. Although controversial, imaging studies may be necessary to confirm a diagnosis of acute bacterial sinusitis in children >6 years of age.

Computed tomography scans of the paranasal sinuses should be reserved for children who present with complications of acute bacterial sinusitis or who have very persistent or recurrent infections and are not responsive to medical management.

Acute bacterial sinusitis should be treated with antimicrobial therapy to achieve a more rapid clinical cure. Children with complications or suspected complications of acute bacterial sinusitis should be treated promptly and aggressively with antibiotics and, when appropriate, drainage.

Background

The ethmoid and the maxillary sinuses form in the third to fourth gestational month and, accordingly, are present at birth. The sphenoid sinuses are generally pneumatized by 5 years of age; the frontal sinuses appear at age 7 to 8 years

but are not completely developed until late adolescence. The paranasal sinuses are a common site of infection in children and most viral infections of the upper respiratory tract involve the nose and the paranasal sinuses (viral rhinosinusitis). However, bacterial infections of the paranasal sinuses do not usually involve the nose. When the patient with bacterial infection of the paranasal sinuses has purulent (thick, colored and opaque) nasal drainage, the site of infection is the paranasal sinuses; the nose is simply acting as a conduit for secretions produced in the sinuses.

The common predisposing events that set the stage for acute bacterial sinusitis are acute viral upper respiratory infections that result in a viral rhinosinusitis (a diffuse mucositis that predisposes to approximately 80 percent of bacterial sinus infections) and allergic inflammation (that predisposes to 20 percent of bacterial sinus infections). Children have 6 to 8 viral upper respiratory infections each year; it is estimated that between 5 to 13 percent of these infections may be complicated by a secondary bacterial infection of the paranasal sinuses.

Definitions

- *Acute Bacterial Sinusitis*: Bacterial infection of the paranasal sinuses lasting less than 30 days in which symptoms resolve completely
- *Subacute bacterial sinusitis*: Bacterial infection of the paranasal sinuses lasting between 30 and 90 days in which symptoms resolve completely
- *Recurrent acute bacterial sinusitis*: Episodes of bacterial infection of the paranasal sinuses, each lasting less than 30 days and separated by intervals of at least 10 days during which the patient is asymptomatic
- *Chronic sinusitis*: Episodes of inflammation of the paranasal sinuses lasting more than 90 days. Patients have persistent residual respiratory symptoms such as cough, rhinorrhea or nasal obstruction

- *Acute bacterial sinusitis superimposed on chronic sinusitis:* Patients with residual respiratory symptoms develop new respiratory symptoms. When treated with antimicrobials, these new symptoms resolve, but the underlying residual symptoms do not.

Etiology

- *Streptococcus pneumoniae* (30%), *Haemophilus influenzae* (20%), *Moraxella catarrhalis* (20%) are major causes. Uncommon causes include *Staphylococcus aureus*, other streptococci, and anaerobes. *H. influenzae*, β -hemolytic streptococci, *M. catarrhalis*, *S. pneumoniae* and coagulase -ve staph are commonly recovered from children with chronic sinus disease
- Predisposing factors are viral upper respiratory infection, allergic rhinitis, cigarette smoke exposure, immune deficiencies (particularly IgG), cystic fibrosis, abnormalities of phagocyte function, GE reflux, anatomic defects (cleft palate), nasal polyps and nasal foreign bodies. Immunosuppression for bone marrow transplantation or malignancy with profound neutropenia and lymphopenia predisposes to severe fungal (*Aspergillus*, mucor) sinusitis, often with intracranial extension. Patients with nasotracheal intubation and nasogastric tubes may have obstruction of the sinus ostia and develop sinusitis with multiple drug resistant organisms of ICU.

Clinical Manifestations

Children with severe onset of acute bacterial sinusitis may have an intense headache that is above or behind the eye; in general, they seem to be moderate. Unfortunately, the physical examination does not generally contribute substantially to the diagnosis of acute bacterial sinusitis. This is explained by the similarity of physical findings in the patient with an uncomplicated viral rhinosinusitis and the patient with acute bacterial sinusitis. In both instances, examination of the nasal mucosa may show mild erythema and swelling of the nasal turbinates with mucopurulent discharge.

Facial pain is an unusual complaint in children. Facial tenderness is a rare finding in small children and may be unreliable as an indicator of acute bacterial sinusitis in older children and adolescents. Reproducible unilateral pain, present on percussion or direct pressure over the body of the frontal and maxillary sinuses, may indicate a diagnosis of acute bacterial sinusitis. Likewise, observed or reported periorbital swelling is suggestive of ethmoid sinusitis. Low-grade fever may be periodic but is usually not prominent.

Diagnosis

For children 6 years of age or younger, because a positive history predicts the finding of abnormal sinus radiographs so frequently (and because history plus abnormal

radiographs results in a positive sinus aspirate in 75% of cases), radiographs can be safely omitted and a diagnosis of acute bacterial sinusitis can be made on clinical criteria alone.

In children older than 6 years the American College of Radiology has taken the position that the diagnosis of acute uncomplicated sinusitis should be made on clinical grounds. They support this position by noting that plain radiographs of the paranasal sinuses are technically difficult to perform, particularly in very young children alone. It is essential to recognize that abnormal images of the sinuses (either radiographs, CT scan or magnetic resonance imaging) cannot stand alone as diagnostic evidence of acute bacterial sinusitis under any circumstances.

Images can serve only as confirmatory measures of sinus disease in patients whose clinical histories are supportive of the diagnosis. Numerous investigations have demonstrated the high frequency of abnormal images in the paranasal sinuses of children undergoing imaging for indications other than suspected sinusitis. <http://aappolicy.aappublications.org/cgi/content/full/pediatrics;108/3/748-838>. Computed tomography scans are indicated in children who present with complications of acute bacterial sinus infection or those who have very persistent or recurrent infections that are not responsive to medical management. In these instances, the image, preferably a complete CT scan of the paranasal sinuses, is essential to provide precise anatomic information to the clinician. These are instances in which the physician may be contemplating surgical intervention, including aspiration of the paranasal sinuses.

Patients with recurrent acute bacterial sinusitis are defined as having had 3 episodes of acute bacterial sinusitis in 6 months or 4 episodes in 12 months. The response to antibiotics is usually brisk and the patient is completely free of symptoms between episodes.

Persistent symptoms are those that last longer than 10 to 14, but less than 30 days. Such symptoms include nasal or postnasal discharge (of any quality), day time cough (which may be worse at night), or both.

Severe symptoms include a temperature of at least 102°F (39°C) and purulent nasal discharge present concurrently for at least 3 to 4 consecutive days in a child who seems ill.

The child who seems toxic should be hospitalized and is not considered in this algorithm. It is the concurrent presentation with high fever and purulent nasal discharge for at least 3 to 4 consecutive days that helps to define the severe presentation of acute bacterial sinusitis.

Sinus aspirate culture is the only accurate method but is not practical for routine use of immunocompetent patients. It may be necessary for immunocompromised patients with suspected fungal sinusitis. To promote the judicious use of antibiotics, it is essential that children diagnosed as having acute bacterial sinusitis meet the

defining clinical presentations of “persistent” or “severe” disease as described previously.

Transillumination of the sinus cavities may demonstrate the presence of fluid but cannot reveal whether it is viral or bacterial in origin. In children it is difficult to perform and unreliable.

Treatment

American Academy of Pediatrics (AAP) recommends antimicrobial treatment for acute bacterial sinusitis to promote resolution of symptoms and prevent suppurative complications, although 50 to 60 percent of children recover without antimicrobial therapy. To promote the judicious use of antibiotics, it is essential that children diagnosed as having acute bacterial sinusitis meet the defining clinical presentations of “persistent” or “severe” disease as described previously (Flow chart 1). Currently, approximately 50 percent of *H. influenzae* and 100 percent of *M. catarrhalis* are likely to be β -lactamase positive nationwide. Upper respiratory tract isolates of *S. pneumoniae* are not susceptible to penicillin in 15 to 38 percent (average 25%) of children; approximately 50 percent are highly resistant to penicillin and the remaining half are intermediate in resistance. The mechanism of penicillin resistance in *S. pneumoniae* is an alteration of penicillin binding proteins. The desire to continue to use amoxicillin as first-line therapy in patients suspected of having acute bacterial sinusitis relates to its general effectiveness, safety, and tolerability; low cost, and narrow spectrum.

For children younger than 2 years of age with uncomplicated acute bacterial sinusitis that is mild to moderate in degree of severity, who do not attend day care, and have not recently been treated with an antimicrobial, amoxicillin is recommended at either a usual dose of 45 mg/kg/d in 2 divided doses or a high dose of 90 mg/kg/d in 2 divided doses. If the patient is allergic to amoxicillin, either cefdinir (1 mg/kg/d in 1 or 2 doses), cefuroxime (30 mg/kg/d in 2 divided doses), or cefpodoxime (10 mg/kg/d once daily) can be used (only if the allergic reaction was not a type 1 hypersensitivity reaction). In cases of serious allergic reactions, clarithromycin (15 mg/kg/d in 2 divided doses) or azithromycin (10 mg/kg/d on day 1, 5 mg/kg/d \times 4 days as a single daily dose) can be used in an effort to select an antimicrobial of an entirely different class.

The food and drug administration has not approved azithromycin for use in patients with sinusitis. Alternative therapy in the penicillin-allergic patient who is known to be infected with a penicillin-resistant *S. pneumoniae* is clindamycin at 30 to 40 mg/kg/d in 3 divided doses.

Most patients with acute bacterial sinusitis who are treated with an appropriate antimicrobial agent respond promptly (within 48-72 hours) with a diminution of respiratory symptoms (reduction of nasal discharge and cough) and an improvement in general well-being. If a patient fails to improve, either the antimicrobial is ineffective or the diagnosis of sinusitis is not correct.

If patients do not improve while receiving the usual dose of amoxicillin (45 mg/kg/d), have recently been treated with an antimicrobial, have an illness that is moderate or more severe, or attend day care, therapy should be initiated with high-dose amoxicillin-clavulanate (80-90 mg/kg/d of amoxicillin component, with 6.4 mg/kg/d of clavulanate in 2 divided doses). This dose of amoxicillin will yield sinus fluid levels that exceed the minimum inhibitory concentration of all *S. pneumoniae* that are intermediate in resistance to penicillin and most, but not all, highly resistant *S. pneumoniae*. There is sufficient potassium clavulanate to inhibit all β -lactamase producing *H. influenzae* and *M. catarrhalis*. Alternative therapies include cefdinir, cefuroxime, or cefpodoxime.

A single dose of ceftriaxone (at 50 mg/kg/d), given either intravenously or intramuscularly, can be used in children with vomiting that precludes administration of oral antibiotics. Twenty-four hours later, when the child is clinically improved, an oral antibiotic is substituted to complete the therapy.

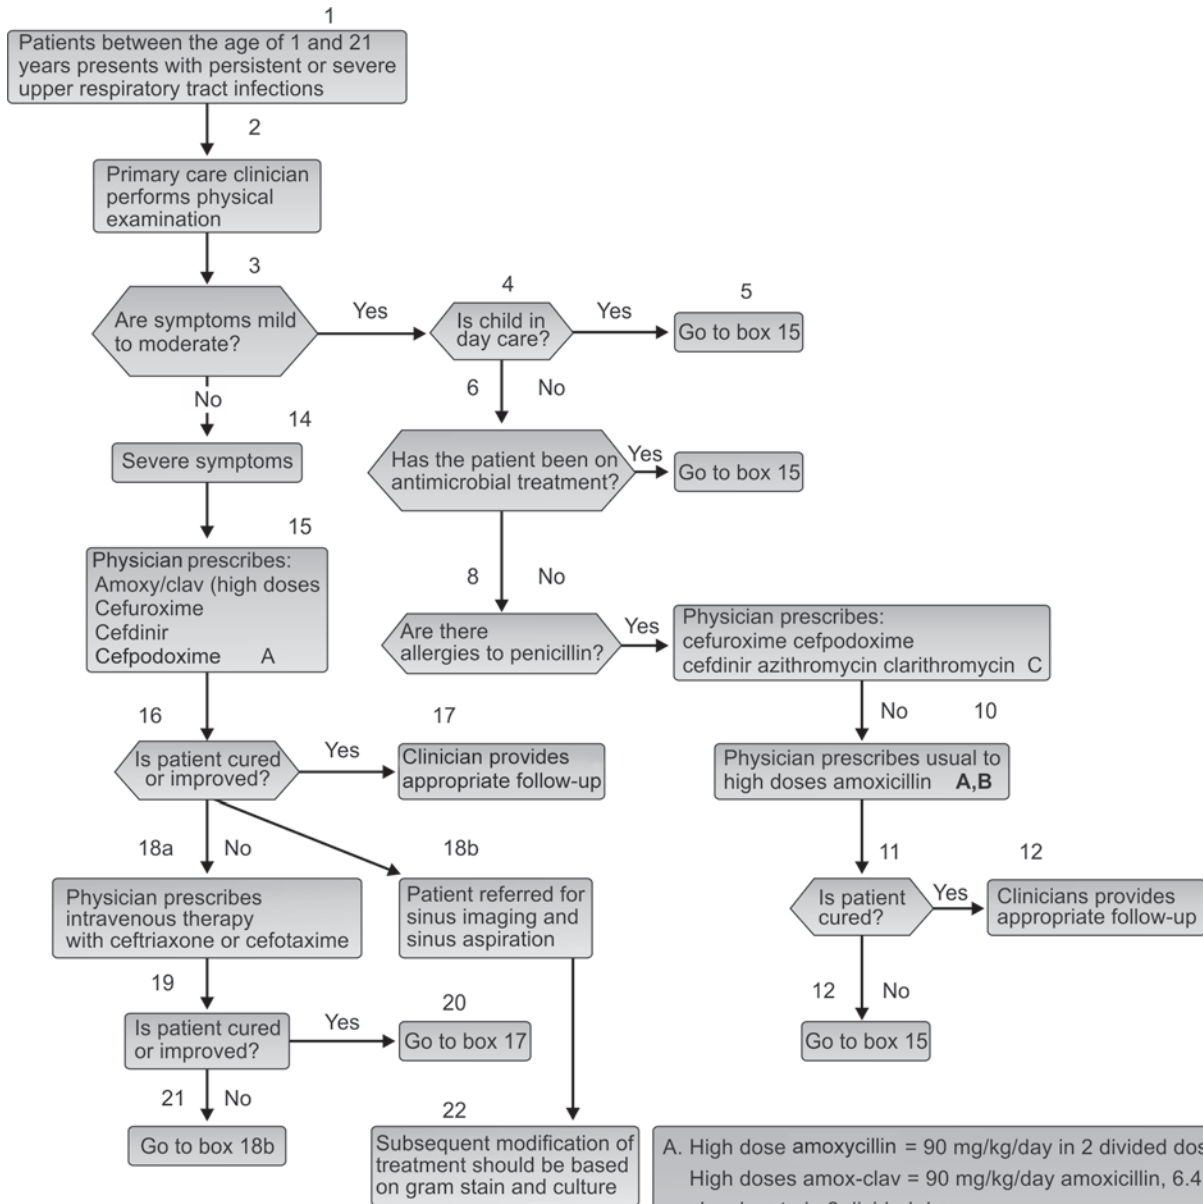

For patients who do not improve with a second course of antibiotics or who are acutely ill, there are 2 options. It is appropriate to consult an otolaryngologist for consideration of maxillary sinus aspiration to obtain a sample of sinus secretions for culture and sensitivity so that therapy can be adjusted precisely. Alternatively, the physician may prescribe intravenous cefotaxime or ceftriaxone (either in hospital or at home) and refer to an otolaryngologist only if the patient does not improve on intravenous antibiotics. Some authorities recommend performing cultures of the middle meatus instead of aspiration of the maxillary sinus to determine the cause of acute bacterial sinusitis. However, there are no data in children that have correlated cultures of the middle meatus with cultures of the maxillary sinus aspirate. <http://aapolicy.aappublications.org/cgi/content/full/pediatrics;108/3/798-854>.

The optimal duration of therapy for patients with acute bacterial sinusitis has not received systematic study. Often empiric recommendations are made for 10, 14, 21, or 28 days of therapy. An alternative suggestion has been made that antibiotic therapy be continued until the patient becomes free of symptoms and then for an additional 7 days. This strategy, which individualizes treatment for each patient, results in a minimum course of 10 days and avoids prolonged courses of antibiotics in patients who are asymptomatic and thereby unlikely to be compliant.

The use of decongestants, antihistaminics, mucolytics and intranasal corticosteroids have not been adequately studied in children and are not recommended for the treatment of acute uncomplicated bacterial sinusitis.

Complications

The complications of acute bacterial sinusitis usually involve either the orbit, the central nervous system, or both. Although rare, complications can result in

Flow chart 1: Management of a child between 1 year and 21 years with source acute upper respiratory tract infection

- A. High dose amoxycillin = 90 mg/kg/day in 2 divided doses.
High doses amox-clav = 90 mg/kg/day amoxicillin, 6.4 mg/kg/day clavulanate in 2 divided doses.
- B. Usual doses amoxicillin=45 mg/kg/day in 2 divided doses
- C. Most patients with allergy to penicillin will tolerate cephalosporins.
If allergy manifests as anaphylaxis, macrolides should be prescribed instead of cephalosporins:
1. Cefuroxime 30 mg/kg/day in 2 divided doses
 2. Cefpodoxime 10 mg/kg/day once daily
 3. Cefdinir 14 mg/kg/day once daily
 4. Azithromycin 10 mg/kg/day on day 1; 5mg/kg single daily dose for 4 days
 5. Clarithromycin 15 mg/kg/day in 2 divided doses

permanent blindness or death if not treated promptly and appropriately.

Periorbital and intraorbital inflammation and infection are the most common complications of acute sinusitis and most often are caused by acute ethmoiditis. These disorders are commonly classified in relation to the orbital septum. The orbital septum is a sheet of connective tissue continuous with the periosteum of the orbital bones that separates tissues of the eyelid from those of the orbit. Preseptal inflammation involves only the eyelid, whereas postseptal inflammation involves structures of the orbit. Complications can be classified as 1) periorbital (or preseptal) cellulitis or sympathetic edema (periorbital cellulitis is not a true orbital complication. The periorbital swelling is attributable to passive venous congestion; infection is confined to the paranasal sinuses, 2) subperiosteal abscess, 3) orbital abscess, 4) orbital cellulitis, or 5) cavernous sinus thrombosis.

Mild cases of periorbital cellulitis (eyelid <50% closed) may be treated with appropriate oral antibiotic therapy as an outpatient with daily patient encounters. However, if the patient has not improved in 24 to 48 hours or if the infection is progressing rapidly, it is appropriate to admit the patient to the hospital for antimicrobial therapy consisting of intravenous ceftriaxone (100 mg/kg/d in 2 divided doses) or ampicillin-sulbactam (200 mg/kg/d in 4 divided doses). Vancomycin (60 mg/kg/d in 4 divided doses) may be added in children in whom infection is either known or likely to be caused by *S. pneumoniae* that are highly resistant to penicillin. If proptosis, impaired visual acuity, or impaired extraocular mobility are present on examination, a CT scan (preferably coronal thin cut with contrast) of the orbits/sinuses is essential to exclude a suppurative complication. In such cases, the patient should be evaluated by an otolaryngologist and an ophthalmologist.

Suppurative complications generally require prompt surgical drainage. An exception to this is the patient with a small subperiosteal abscess and minimal ocular abnormalities for whom intravenous antibiotic treatment for 24 to 48 hours is recommended while performing frequent visual and mental status checks. Patients who have changes in visual acuity or mental status or who fail to improve within 24 to 48 hours require prompt surgical intervention and drainage of the abscess. Antibiotics can be altered, if inappropriate, when results of culture and sensitivity studies become available.

In patients with altered mental status, neurosurgical consultation is indicated. Signs of increased intracranial pressure (headache and vomiting) or nuchal rigidity require immediate CT scanning (with contrast) of the brain, orbits, and sinuses to exclude intracranial complications such as cavernous sinus thrombosis, osteomyelitis of the frontal bone (Pott's puffy tumor), meningitis, subdural empyema, epidural abscess and brain abscess. Central

nervous system complications, such as meningitis and empyemas should be treated either with intravenous cefotaxime or ceftriaxone and vancomycin pending the results of culture and susceptibility testing.

Other complications include osteomyelitis of the frontal bone (*Pott puffy tumor*), which is characterized by edema and swelling of the forehead and *mucoceles*, which are chronic inflammatory lesions commonly located in the frontal sinuses that can expand, causing displacement of the eye with resultant diplopia. Surgical drainage is usually required.

Conclusion

This clinical practice guideline provides evidence-based recommendations for the management of bacterial rhinosinusitis in children ages 1 to 21 years. The guideline emphasizes

- Appropriate diagnosis in children who present with persistent or severe upper respiratory symptoms
- The utility of imaging studies to confirm a diagnosis
- Treatment therapies such as antibiotic use including prophylaxis, adjuvant treatment, and alternative interventions
- Management of complications.

The guideline provides decision-making strategies for managing sinusitis to assist primary care providers in diagnosing and treating children with this common health problem.

OTITIS MEDIA

Otitis media (OM) figures importantly in differential diagnosis of fever in children. Its peak incidence and prevalence is from 6 to 20 months of age. An important characteristic of OM is its propensity to become chronic and recur. The earlier in life a child experiences the 1st episode, the greater the degree of subsequent difficulty in terms of frequency of recurrence, severity and persistence of middle ear effusion.

The term *otitis media* has 2 main components: acute or suppurative otitis media (AOM); and inflammation accompanied by effusion termed nonsuppurative or secretory otitis media or otitis media with effusion (OME). These two are interrelated. Middle ear effusion is a feature of both AOM and OME.

Definition

- A diagnosis of AOM requires
 - A history of acute onset of signs and symptoms,
 - The presence of MEE, and
 - Signs and symptoms of middle-ear inflammation
 Elements of the definition of AOM are all of the following
- Recent, usually abrupt, onset of signs and symptoms of middle-ear inflammation and MEE

The presence of MEE that is indicated by any of the following

- Bulging of the tympanic membrane
- Limited or absent mobility of the tympanic membrane
- Air-fluid level behind the tympanic membrane
- Otorrhea
- Signs or symptoms of middle-ear inflammation as indicated by either
 - Distinct erythema of the tympanic membrane or
 - Distinct otalgia (discomfort clearly referable to the ear[s] that results in interference with or precludes normal activity or sleep).

Epidemiology

Age highest rates during the ages of 6 to 20 months. After 2 years of age the incidence and prevalence of OM decline progressively although the disease remains relatively common into the early school age years. The most likely reasons for higher rates in infants and younger children include less well developed immunologic defenses and less favorable eustachian tubal factors involving both structure and function of the tube. The incidence is greater in boys than girl. Otitis media has a heritable component. There is higher degree of concordance among monozygotic twins than among dizygotics. Poverty, crowding, limited hygienic facilities, suboptimal nutritional status, limited access to medical care, limited resources for complying with prescribed medical regimens are predisposing factors. Breast milk has a protective effect as compared to formula feed. There is a significant link between tobacco smoke and OM. Many studies give a positive correlation between the occurrence of OM and extent of repeated exposure to other children whether at home or out of home day care. The highest rates of occurrence are observed in cold weather and the lowest during warm weather, in keeping with the pattern of URTIs.

Otitis media is universal among infants with unrepaired palatal clefts and also highly prevalent among children with submucous cleft palate, other craniofacial anomalies and Down syndrome. It is due to deficiency in functioning of the eustachian tube.

Vaccination of infants with a conjugate pneumococcal vaccine leads to the modest reduction in the incidence of otitis media.

Etiology

Numerous studies have shown that the common pathogens in AOM are *Streptococcus pneumoniae*, nontypeable *H. influenzae*, and *M. catarrhalis*. *S. pneumoniae* has been recovered from the middle-ear fluid of approximately 25 to 50 percent of children with AOM, *H. influenzae* from 15 to 30 percent, and *M. catarrhalis* from approximately 3 to 20 percent. There is some evidence that the microbiology of AOM may be changing as a result of routine use of the

heptavalent pneumococcal vaccine. Block et al. showed an increase in *H. Influenzae* from 39 to 52 percent of isolates in children 7 to 24 months of age with AOM and a decrease in *S. pneumoniae* from 49 to 34 percent between 1992 to 1998 and 2000 to 2003. Viruses, including respiratory syncytial virus, rhinovirus, coronavirus, parainfluenza, adenovirus, and enterovirus, have been found in respiratory secretions and/or MEE in 40 to 75 percent of AOM cases and in MEE without bacteria in 5 to 22 percent of cases and may be responsible for many cases of apparent antibacterial agent “failure.” In approximately 16 to 25 percent of cases of AOM, no bacterial or viral pathogen can be detected in MEE pathogens typically found in AOM can be recovered in approximately 30 percent of children with OME using standard culture techniques.²

Pathogenesis

In relation to middle ear, eustachian tube has 3 main functions: ventilation, protection and clearance, most important being ventilation. Middle ear mucosa depends on a continuous supply of air from the nasopharynx via eustachian tube. Interruption of this ventilator process by tubal obstruction initiates a complex inflammatory response that includes secretory metaplasia, compromise of mucociliary transport system and effusion of liquid into the tympanic cavity. Impaired middle ear ventilation is an important contributing factor to both AOM and OME.

Eustachian tube obstruction may result extraluminally from hypertrophied nasopharyngeal adenoid tissue, or tumor; or intraluminally, from inflammatory edema of tubal mucosa; most commonly as a consequence of viral URTI; or from impairment of the opening mechanism of tube attributable to abnormal tubal muscular function or excessive tubal wall compliance, or both. Progressive reduction in tubal wall compliance with increasing age may help explain the decline in the occurrence of OM as children grow older. The shorter and more horizontal orientation of the tube in infants and young children may increase the likelihood of reflux from the nasopharynx and impair passive gravitational drainage through the eustachian tube. Another possible explanation for improved eustachian tube function and decreased OM incidence as infants mature is that the luminal diameter increases, reducing the opportunity for tubal obstruction and dysfunction.

In children with cleft palate, where OM is a nearly universal finding, the main factor underlying the chronic middle-ear inflammation is impairment of the opening mechanism of the eustachian tube, due perhaps to greater-than-normal compliance of the tubal wall. Another possible factor is defective velopharyngeal valving, which may result in disturbed aerodynamic and hydrodynamic relationships in the nasopharynx and proximal portions of the eustachian tube. In children with other craniofacial anomalies or with down syndrome, the high prevalence of OM is

attributed to structural and/or functional eustachian tubal abnormalities; histologic evaluation of the eustachian tube in these patient populations demonstrates such abnormalities. Many, if not most, episodes are initiated by a viral or bacterial upper respiratory tract infection. In a study of children in group day care, IgA deficiency is found in some children with recurrent AOM, but its significance is questionable, because IgA deficiency is not uncommon in children without recurrent AOM. Selective IgG subclass deficiencies (despite normal total serum IgG) may be found in children with recurrent AOM in association with recurrent sinopulmonary infection; these deficiencies probably underlie the susceptibility to infection.

Evidence that respiratory allergy is a primary etiologic agent in OM is not convincing, however, in children who have both allergies and OM, it seems possible that the otitis may be aggravated by the allergy.

Ample evidence exists that children with frequent exposure to other children have an increased risk of both nasopharyngeal colonization and acute OM pathology with bacterial types with multiple antimicrobial resistances, making treatment more difficult and prolonged pathology more likely.

Clinical Manifestations

Signs and symptoms of AOM are highly variable, especially in infants and young children. There may be evidence of ear pain, often manifested by irritability, a change in sleeping or eating habits, and, occasionally, holding or tugging at the ear. Pulling at the ear, however, has a low sensitivity and specificity. Fever also may be present and, rarely, rupture of the tympanic membrane with purulent otorrhea. Systemic symptoms and symptoms associated with upper respiratory tract infections also occur, and occasionally there may be no symptoms, with AOM discovered at a routine health examination. OME often is not accompanied by overt complaints of the child but usually is accompanied by hearing loss. This hearing loss may manifest as changes in speech patterns but often goes undetected if it is unilateral or mild, especially in younger children. Balance difficulties or dysequilibrium also can be associated with OME, and older children may complain of mild discomfort or a sense of fullness in the ear (Flow chart 2).

Diagnosis

The presence of MEE is commonly confirmed with the use of pneumatic otoscopy but can be supplemented by tympanometry and/or acoustic reflectometry. MEE also can be demonstrated directly by tympanocentesis or the presence of fluid in the external auditory canal as a result of tympanic membrane perforation.

Visualization of the tympanic membrane with identification of an MEE and inflammatory changes is necessary to establish the diagnosis with certainty. To visualize the

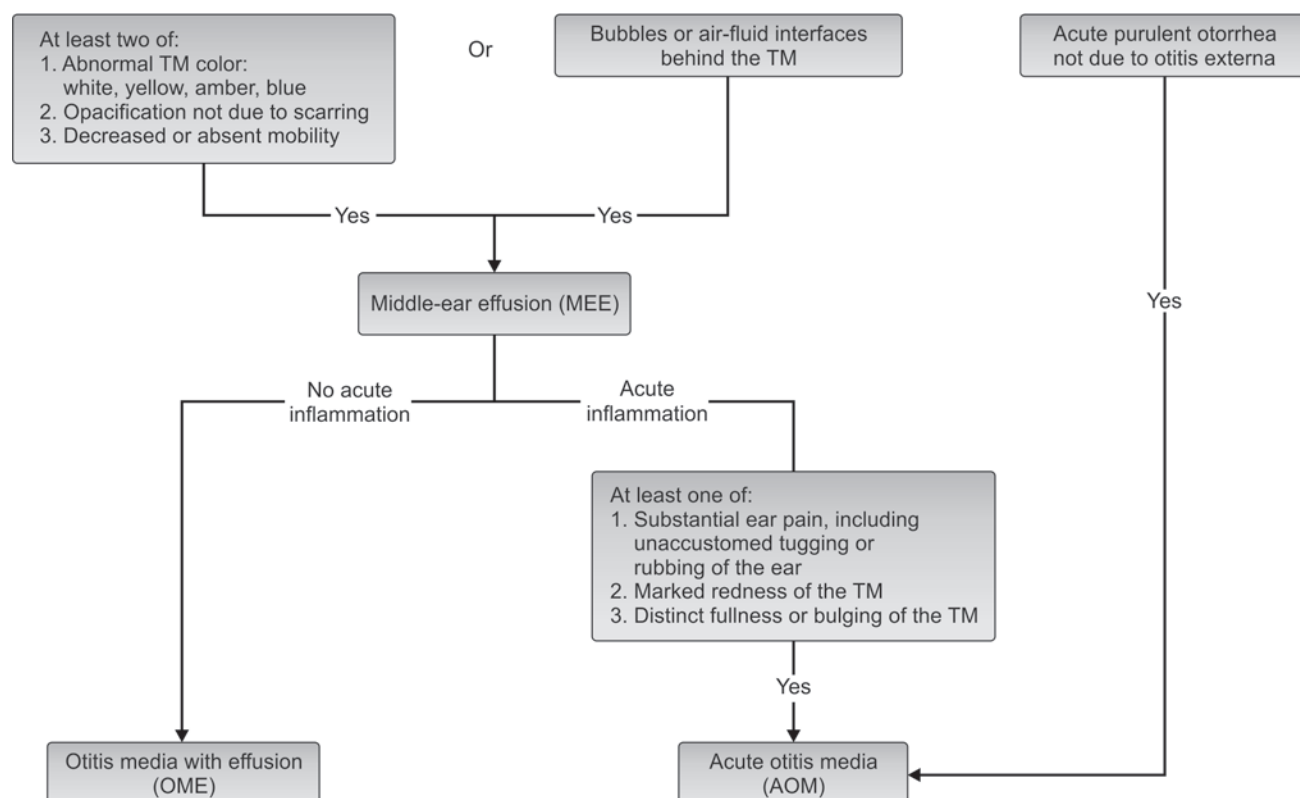

tympanic membrane adequately it is essential that cerumen obscuring the tympanic membrane be removed and that lighting is adequate. For pneumatic otoscopy, a speculum of proper shape and diameter must be selected to permit a seal in the external auditory canal. Appropriate restraint of the child to permit adequate examination may be necessary.

The findings on otoscopy indicating the presence of MEE and inflammation associated with AOM have been well defined. Fullness or bulging of the tympanic membrane is often present and has the highest predictive value for the presence of MEE. When combined with color and mobility, bulging is also the best predictor of AOM. Reduced or absent mobility of the tympanic membrane during performance of pneumatic otoscopy is additional evidence of fluid in the middle ear. Opacification or cloudiness, other than that caused by scarring, is also a consistent finding and is caused by edema of the tympanic membrane. Redness of the tympanic membrane caused by inflammation may be present and must be distinguished from the pink erythematous flush evoked by crying or high fever, which is usually less intense and remits as the child quiets down. In bullous myringitis, blisters may be seen on the tympanic membrane. When the presence of middle-ear fluid is difficult to determine, the use of tympanometry or acoustic reflectometry can be helpful in establishing a diagnosis.

Correct diagnosis of AOM is important to guide clinical treatment decisions. Although in many instances an accurate diagnosis can be made easily, this can be a challenging task, especially with an uncooperative patient. Consensus guidelines defining the required elements for a diagnosis of OM include all of the following elements: (1) recent and usually acute onset of illness, (2) presence of MEE, and (3) signs and symptoms of middle-ear inflammation, including erythema of the tympanic membrane or otalgia. A simplified differentiating schema establishes a diagnosis of AOM when, in addition to having MEE, a child gives evidence of recent, clinically important ear pain or the tympanic membrane shows marked redness or distinct fullness or bulging.

Tympanograms may be grouped into 1 of 3 categories (Figs 1A to C). Tracings characterized by a relatively steep gradient, sharp-angled peak, and middle-ear air pressure (location of the peak in terms of air pressure) that approximate atmospheric pressure (Fig. 1A) (type A curve) are assumed to indicate normal middle-ear status. Tracings characterized by a shallow peak or no peak and by negative or indeterminate middle-ear air pressure, and often termed flat or (type B curve) (Fig. 1B), usually are assumed to indicate the presence of a middle-ear abnormality that is causing decreased tympanic membrane compliance. The most common such abnormality, by far in infants and children, is MEE. Tracings characterized by intermediate findings—a somewhat shallow peak, often in association

Flow chart 2: Distinguishing between acute otitis media (AOM) and otitis media with effusion (OME). Tympanic membrane (TM).

Figs 1A to C: Tympanograms obtained with a Grason-Stadler GSI 33 Middle Ear Analyzer, exhibiting (A) high admittance, steep gradient (i.e. sharp-angled peak), and middle-ear air pressure approximating atmospheric pressure (0 decaPascals [daPa]); (B) low admittance and indeterminate middle-ear air pressure; and (C) somewhat low admittance, gradual gradient, and markedly negative middle-ear air pressure

with a gradual gradient (obtuse-angled peak) or negative middle-ear air pressure, or combinations of these features (Fig. 1C), may or may not be associated with MEE, and must be considered nondiagnostic or equivocal. In general, the more shallow the peak the more gradual the gradient, and the more negative the middle-ear air pressure, the greater the likelihood of MEE.

When reading a tympanogram it is important to look at the volume measurement also provided. A patient with a tympanic membrane perforation or patent tympanostomy tube will have a flat, type B tympanogram and a “high volume.” The tympanometer measures and records the volume of the external auditory canal, and if a tympanic membrane perforation or a patent tympanostomy tube is

present, the volume of the middle ear and mastoid air cells as well. A volume reading of >1.0 ml should suggest the presence of either a perforation or a patent tympanostomy tube. Therefore, in a child with a tympanostomy tube present, a flat tympanogram with a volume <1.0 ml would suggest a plugged or nonfunctioning tube and middle-ear fluid, whereas a flat tympanogram with a volume >1.0 ml would suggest a patent tympanostomy tube.

Although tympanometry is quite sensitive in detecting MEE, it can be limited by patient cooperation, the skill of the individual administering the test, and the age of the child, with less reliable results in very young children. Use of tympanometry may be helpful in office screening, both by obviating the need for routine otoscopic examination in difficult-to-examine patients whose tympanic membranes have been visualized previously, who are asymptomatic, and whose tympanograms are classified as normal, and by identifying patients who require further attention because their tympanograms are abnormal. Tympanometry also may be used to help confirm, refine, or clarify questionable otoscopic findings; to objectify the follow-up evaluation of patients with known middle-ear disease; and to validate otoscopic diagnoses of MEE. Importantly, even though tympanometry can predict the probability of MEE, it cannot distinguish the effusion of OME from that of AOM.

Treatment

Individual episodes of AOM customarily have been treated with antimicrobial drugs. Concern about increases in bacterial resistance has prompted some authors to recommend withholding antimicrobial treatment in some cases unless symptoms persist for 2 to 3 days, or worsen (Table 1).

From subcommittee on management of acute otitis media: Diagnosis and management of acute otitis media (Flow chart 3).

The management of AOM should include an assessment of pain. If pain is present, the clinician should recommend treatment to reduce pain (Table 2). (This is a strong recommendation based on randomized, clinical trials with limitations and a preponderance of benefit over risk.)

First Line Treatment

If a decision is made to treat with an antibacterial agent, the clinician should prescribe amoxicillin for most children. (This recommendation is based on randomized, clinical trials with limitations and a preponderance of benefit over risk.)

When amoxicillin is used, the dose should be 80 to 90 mg/kg per day. (This option is based on extrapolation from microbiologic studies and expert opinion, with a preponderance of benefit over risk.) In patients who have severe illness (moderate to severe otalgia or fever of 39°C or higher) and in those for whom additional coverage for β -lactamase-positive *Hemophilus influenzae* and *Moraxella catarrhalis* is desired, therapy should be initiated with high-dose amoxicillin-clavulanate (90 mg/kg per day of amoxicillin component, with 6.4 mg/kg per day of clavulanate in 2 divided doses). This dose has sufficient potassium clavulanate to inhibit all β -lactamase-producing *H. influenzae* and *M. catarrhalis*.

Currently approximately 50 percent of isolates of *H. influenzae* and 100 percent of *M. catarrhalis* derived from the upper respiratory tract are likely to be β -lactamase-positive nationwide. Between 15 percent and 50 percent (average: 30%) of upper respiratory tract isolates of *S. pneumoniae* are also not susceptible to penicillin; approximately 50 percent of these are highly resistant to penicillin (minimum inhibitory concentration: $2.0\text{ }\mu\text{g/mL}$ or higher), and the remaining 50% are intermediate in resistance (minimum inhibitory concentration: between 0.1 and $1.0\text{ }\mu\text{g/mL}$). The mechanism of penicillin resistance among isolates of *S. pneumoniae* is not associated with β -lactamase production but rather an alteration of penicillin-binding proteins. This phenomenon, which varies considerably according to geographic location, results in resistance to penicillins and cephalosporins. The patient is allergic to amoxicillin and the allergic reaction was not a type I hypersensitivity reaction (urticaria or anaphylaxis), cefdinir (14 mg/kg per day in 1 or 2 doses), cefpodoxime (10 mg/kg per day, once daily), or cefuroxime (30 mg/kg per day in 2 divided doses) can be used. In cases of type I reactions, azithromycin (10 mg/kg per day

Table 1: Criteria for initial antibacterial-agent treatment or observation in children with AOM

Age	Certain Diagnosis	Uncertain Diagnosis
<6 months	Antibacterial therapy	Antibacterial therapy
6 months–2 years	Antibacterial therapy	Antibacterial therapy if severe illness; observation option* if nonsevere illness
≥ 2 years	Antibacterial therapy if severe illness; observation option* if nonsevere illness	Observation option*

*Observation is an appropriate option only when follow-up can be ensured and antibacterial agents started if symptoms persist or worsen. Nonsevere illness is mild otalgia and fever $<39^{\circ}\text{C}$ in the past 24 hours. Severe illness is moderate to severe otalgia or fever $\geq 39^{\circ}\text{C}$. A certain diagnosis of AOM meets all 3 criteria: (1) rapid onset, (2) signs of MEE, and (3) signs and symptoms of middle-ear inflammation.

Table 2: Methods of handling pain in AOM

<i>Modality</i>	<i>Comments</i>
Acetaminophen, ibuprofen	Effective analgesia for mild to moderate pain, readily available, mainstay of pain management for AOM
Home remedies (no controlled studies that directly address effectiveness)	May have limited effectiveness
Distraction	
External application of heat or cold	
Oil	
Topical agents	
Benzocaine (auralgan, americaine otic)	Additional but brief benefit over acetaminophen in patients >5 y
Naturopathic agents (otikon otic solution)	Comparable with ametocone/ phenazone drops (Anesthetic) in patients >6 y
Homeopathic agents	No controlled studies that directly address pain
Narcotic analgesia with codeine or analogs	Effective for moderate or severe pain; requires prescription; risk of respiratory depression, altered mental status, gastrointestinal upset, and constipation
Tympanostomy/ myringotomy	Requires skill and entails potential risk

on day 1 followed by 5 mg/ kg per day for 4 days as a single daily dose) or clarithromycin (15 mg/ kg per day in 2 divided doses) can be used in an effort to select an antibacterial agent of an entirely different class. Other possibilities include erythromycin-sulfisoxazole (50 mg/kg per day of erythromycin) or sulfamethoxazole-trimethoprim (6–10 mg/kg per day of trimethoprim). Alternative therapy in the penicillin-allergic patient who is being treated for infection that is known or presumed to be caused by penicillin-resistant *S. pneumoniae* is clindamycin at 30 to 40 mg/kg per day in 3 divided doses. In the patient who is vomiting or cannot otherwise tolerate oral medication, a single dose of parenteral ceftriaxone (50 mg/kg) has been shown to be effective for the initial treatment of AOM.

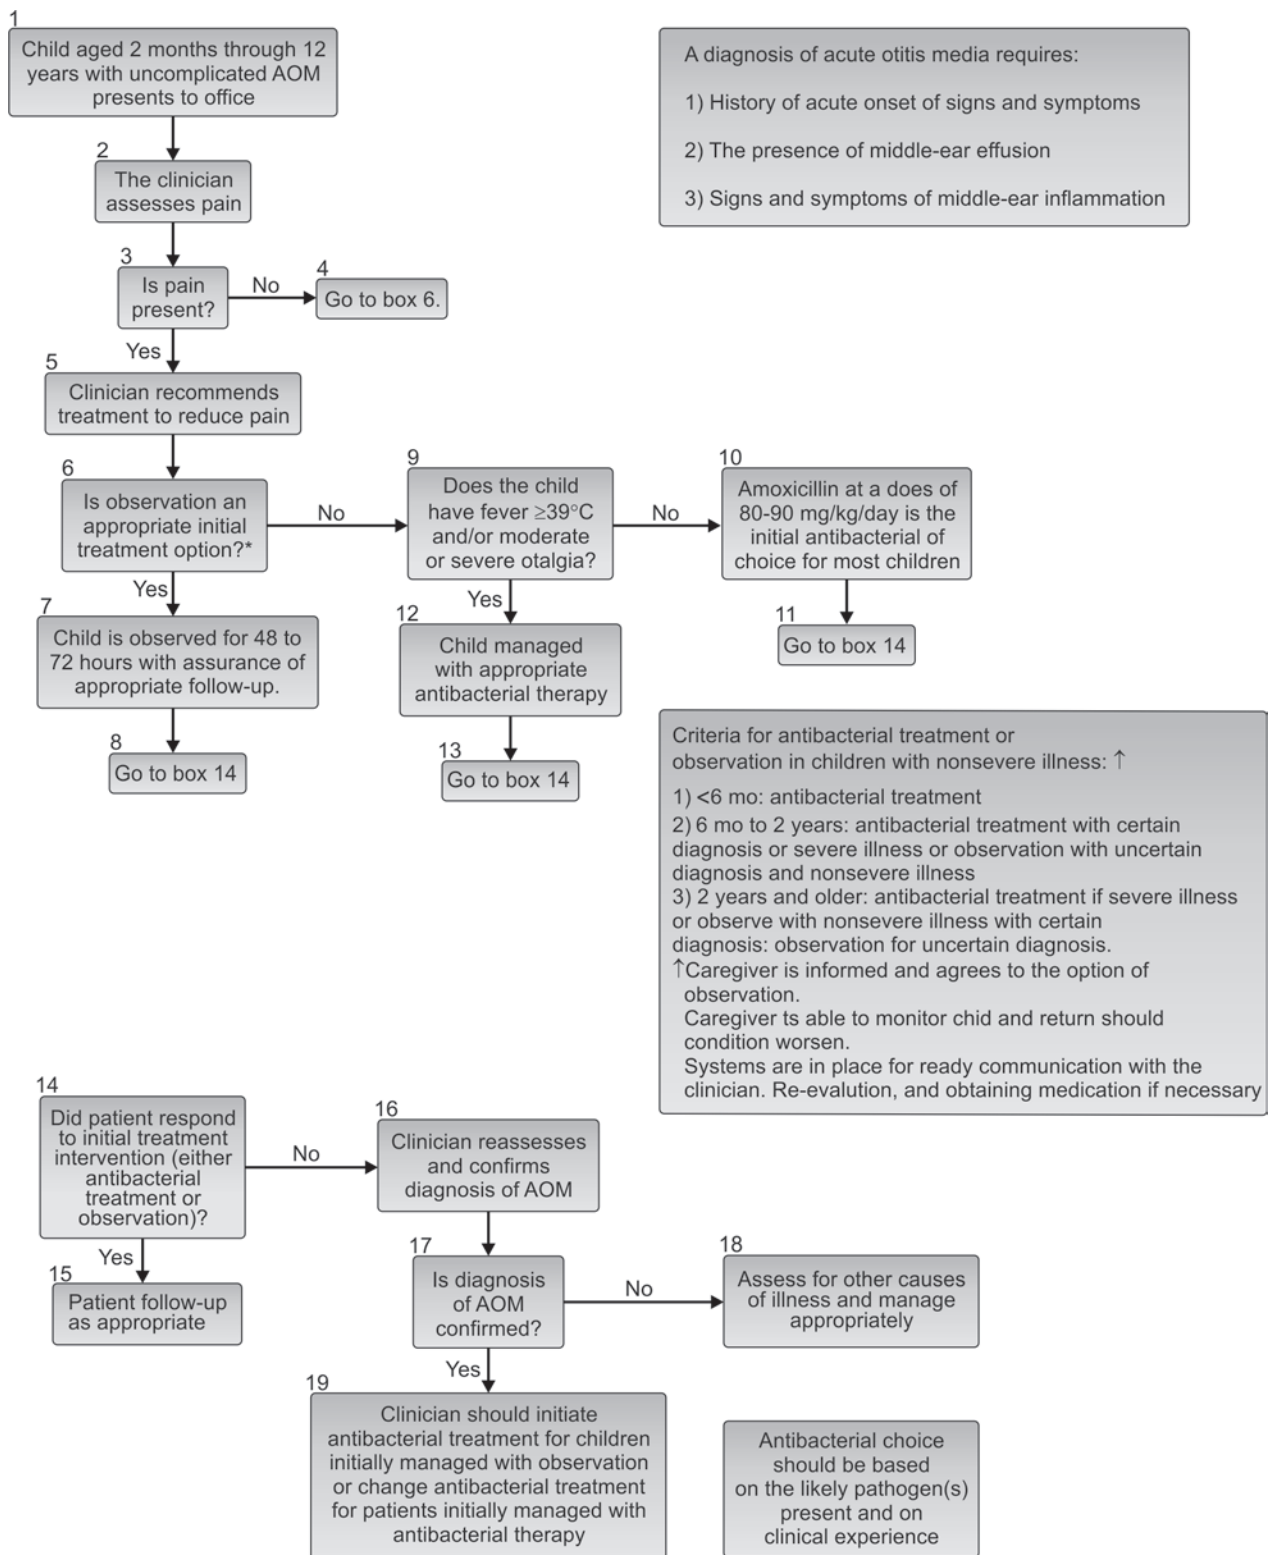

The optimal duration of therapy for patients with AOM is uncertain. Studies comparing standard duration of treatment (10 days) to short-duration treatment (1–7 days) were often characterized by limitations including inadequate sample size (therefore, having low or limited statistical power), few or no children younger than 2 years, exclusion of otitis-prone children, lack of standardized or stringent criteria for the diagnosis of AOM or for improvement or cure, use of an antibacterial medication that had less than optimal efficacy against common middle-ear pathogens, use of lower than recommended dosage of a medication, and lack of analysis of outcome by age. Not surprisingly, the results of these studies were variable. Several more recent studies have been reported that addressed the issue of duration of therapy. The results favoring standard 10-day therapy have been most significant in children younger than 2 years and suggestive of

increased efficacy in those 2 to 5 years of age. Thus, for younger children and for children with severe disease, a standard 10-day course is recommended. For children 6 years of age and older with mild to moderate disease, a 5 to 7 days course is appropriate.

Second-Line Treatment

If the patient fails to respond to the initial management option within 48 to 72 hours, the clinician must reassess the patient to confirm AOM and exclude other causes of illness. If AOM is confirmed in the patient initially managed with observation, the clinician should begin antibacterial therapy. If the patient was initially managed with an antibacterial agent, the clinician should change the antibacterial agent.

Antibacterial agent choice after initial failure of observation or first-line antibacterial therapy should be based on the likely pathogen(s) present and on clinical experience. If the patient was treated with initial observation, amoxicillin should be started at a dose of 80 to 90 mg/ kg per day. For patients who have severe illness (moderate to severe otalgia or temperature of 39°C or higher), in those for whom additional coverage for β -lactamase-positive *H. influenzae* and *M. catarrhalis* is desired, and for those who had been treated initially with amoxicillin and did not improve, high-dose amoxicillin-clavulanate (90 mg/kg per day of amoxicillin component, with 6.4 mg/ kg per day of clavulanate in 2 divided doses) should be used. Alternatives in patients with a history of a non-type I allergic reaction to penicillins are cefdinir, cefpodoxime, or cefuroxime. In cases of type I reactions, alternatives are

Flow chart 3: Management of AOM: Diagnosis and management of Acute Otitis Media. Pediatrics 2004;113:1451-1465.

azithromycin, clarithromycin, erythromycin-sulfisoxazole, or sulfamethoxazole-trimethoprim. Ceftriaxone (50 mg/kg per day), given for 3 consecutive days either intravenously or intramuscularly, can be used in children with vomiting or in other situations that preclude administration of oral antibacterial agents. In the treatment of AOM unresponsive to initial antibacterial therapy, a 3-day course of ceftriaxone has been shown to be better than a 1-day regimen. Although trimethoprim-sulfamethoxazole and erythromycin-sulfisoxazole have traditionally been useful as first- and second-line therapy for patients with AOM, recent pneumococcal surveillance studies indicate that resistance to these 2 combination agents is substantial. Therefore, when patients fail to improve while receiving amoxicillin, neither trimethoprim-sulfamethoxazole nor erythromycin-sulfisoxazole is optimal for antibacterial therapy.

- A patient who fails amoxicillin-potassium clavulanate should be treated with a 3-day course of parenteral ceftriaxone because of its superior efficacy against *S. pneumoniae*, compared with alternative oral antibacterials. If AOM persists, tympanocentesis should be recommended to make a bacteriologic diagnosis. If tympanocentesis is not available, a course of clindamycin may be considered for the rare case of penicillin-resistant pneumococcal infection not responding to the previous regimens. If the patient still does not improve, tympanocentesis with gram-stain, culture, and antibacterial-agent sensitivity studies of the fluid is essential to guide additional therapy.

Indications for myringotomy in children with AOM include severe, refractory pain, hyperpyrexia, complications of AOM such as facial paralysis, mastoiditis, labyrinthitis, or central nervous system infection; and immunologic compromise. Myringotomy should be considered as third-line therapy in patients who have failed 2 courses of antibiotics for an episode of AOM. In children with AOM in whom clinical response to vigorous, second-line treatment has been unsatisfactory, either diagnostic tympanocentesis or myringotomy is indicated to enable identification of the offending organism and its sensitivity profile.

When a patient requires 3 to 4 courses of antibiotics for episodes of AOM in a 6-months period or 5 to 6 episodes in a 12-months period, potential surgical management of the child's AOM should be discussed with the parents.

Management of Otitis Media with Effusion

To determine the course of an episode of OME, and to distinguish between persistence and recurrence, examination should be conducted monthly until resolution, and hearing should be assessed if effusion has been present for >3 months. Although hearing loss may be of primary concern, OME causes a number of other difficulties in children that also should be considered. These include predisposition to recurring AOM, pain, disturbance of

balance, and tinnitus. Long-term sequel that have been demonstrated to be associated with OME include pathologic middle-ear changes; atelectasis of the tympanic membrane and retraction pocket formation, adhesive OM, ossicular discontinuity, cholesteatoma, and conductive and sensorineural hearing loss. Long-term adverse effects on speech, language, and cognitive and psychosocial development also are noted. Children with OME persisting >3 months deserve close monitoring of their hearing levels with skilled audiologic evaluation; frequent assessment of developmental milestones, including speech and language assessment; and attention paid to their rate of recurrent AOM.

Medical Treatment

Antimicrobials have definite but limited efficacy in resolving OME, presumably because they help eradicate nasopharyngeal infection or inapparent middle-ear infection, or both. However, mainly because of the short-term nature of their benefit and because of the contribution of antimicrobial usage to the development of bacterial resistance, routine antimicrobial treatment of OME, previously recommended by some authorities, no longer seems wise. Instead, treatment should be limited to cases in which there is evidence of associated bacterial upper respiratory tract infection or untreated middle-ear infection. For this purpose, the most broadly effective drug available should be used, as recommended for AOM.

The efficacy of oral corticosteroids in the treatment of OME is probably short-term at best, and guidelines for the treatment of OME have determined that the risk-benefit ratio for these medications would argue against their use. Antihistamine-decongestant combinations are not effective in treating children with OME, but their efficacy has not been tested in children with environmental allergies. Antihistamines alone, decongestants alone, and mucolytic agents are unlikely to be effective.

Myringotomy and Insertion of Tympanostomy Tubes

When OME persists despite an ample period of watchful waiting, usually 3 to 6 months or perhaps longer in children with unilateral effusion, the question arises as to surgical intervention. Myringotomy alone, without tympanostomy tube insertion, permits evacuation of middle-ear effusion and sometimes is effective; often, because the incision heals before the middle-ear mucosa returns to normal the effusion soon reaccumulates. Inserting tubes offers the likelihood that middle-ear ventilation will be sustained for at least as long as the tube remains in place and functional, about 12 months on average, and nearly uniformly reverses the conductive hearing loss associated with OME. Occasional episodes of obstruction of the tube lumen and premature tube extrusion may limit the effectiveness of tympanostomy

tubes, and tubes also can be associated with otorrhea. However, placement of tympanostomy tubes usually is effective in providing resolution of OME in children. Sequel following tubal extrusion include residual perforation of the eardrum, tympanosclerosis, localized or diffuse atrophic scarring of the eardrum that may predispose to the development of atelectasis or a retraction pocket or both, residual conductive hearing loss, and cholesteatoma. Fortunately, the more serious of these sequel occur infrequently.

Complications of Acute Otitis Media

Intratemporal Complications

Infectious dermatitis

Infectious dermatitis is an infection of the skin of the external auditory canal resulting from contamination by purulent discharge from the middle-ear. The skin often is erythematous, edematous, and tender. Management consists of proper hygiene combined with systemic antimicrobials and ototopical drops as appropriate for treating AOM and tube otorrhea.

Tympanic membrane perforation

Rupture of the tympanic membrane can occur with episodes of either AOM or OME. Although damage to the tympanic membrane from these episodes usually heals spontaneously, chronic perforations can develop in a small number of cases and require further surgical intervention.

Chronic suppurative otitis media

Chronic suppurative OM consists of persistent middle-ear infection with discharge through a tympanic membrane perforation. The disease is initiated by an episode of AOM with rupture of the membrane. The mastoid air cells always are involved. The most common etiologic organisms are *P. aeruginosa* and *S. aureus*. Treatment is guided by the results of microbiologic investigation. If an associated cholesteatoma is not present, parenteral antimicrobial treatment combined with assiduous aural cleansing is likely to be successful in clearing the infection, but in refractory cases, tympanomastoidectomy can be required.

Acute mastoiditis

Technically, all cases of AOM are accompanied by mastoiditis by virtue of the associated inflammation of the mastoid air cells. However, early in the course of the disease no signs or symptoms of mastoid infection are present, and the inflammatory process usually is readily reversible, along with the AOM, in response to antimicrobial treatment. Spread of the infection to the overlying periosteum, but without involvement of bone, constitutes *acute mastoiditis with periosteitis*. In such cases, signs of mastoiditis usually are present, i.e., inflammation in the postauricular area, often with displacement of the pinna inferiorly and

anteriorly. Treatment with myringotomy and parenteral antibiotics, if instituted promptly, usually provides satisfactory resolution. In acute mastoid osteitis, or coalescent mastoiditis, infection has progressed further, causing destruction of the bony trabeculae of the mastoid. Frank signs and symptoms of mastoiditis usually, but not always, are present. In acute petrositis, infection has extended further to involve the petrous portion of the temporal bone. Eye pain is a prominent symptom, due to irritation of the ophthalmic branch of the cranial nerve V; cranial nerve VI palsy later develops. *Gradenigo syndrome* is the triad of suppurative OM, paralysis of the external rectus muscle, and pain in the ipsilateral orbit. Rarely, mastoid infection spreads to the neck muscles that attach to the mastoid tip, resulting in an abscess in the neck, termed a *Bezold abscess*. When mastoiditis is suspected or diagnosed clinically, CT scanning of the temporal bone should be carried out to further clarify the nature and extent of the disease. Bony destruction of the mastoid must be differentiated from the simple clouding of mastoid air cells that often is found in uncomplicated cases of OM. The most common causative organisms in all variants of acute mastoiditis is *S. pneumoniae*, nontypable *H. influenzae*, and *P. aeruginosa*. Children with acute mastoid osteitis require intravenous antimicrobial treatment and mastoidectomy, with the extent of the surgery depending on the extent of the disease process:

- Each of the variants of mastoiditis also may occur in subacute or chronic form. Symptoms are correspondingly less prominent. Chronic mastoiditis always is accompanied by chronic suppurative OM, and occasionally will respond to the conservative regimen recommended for that condition. In most cases, however, mastoidectomy also is required.

Facial paralysis

The facial nerve, as it traverses the middle-ear and mastoid bone, may be affected by adjacent infection. Facial paralysis as a complication of AOM is uncommon, and often resolves after myringotomy and parenteral antibiotic treatment. Facial paralysis in the presence of AOM requires urgent attention, because prolonged infection can result in permanent facial paralysis, which, when it occurs, can have a devastating affect on a child. If facial paralysis develops in a child with mastoid osteitis or with chronic suppurative OM, mastoidectomy should be undertaken urgently.

Acquired cholesteatoma

Cholesteatoma is a cyst like growth within the middle-ear or other pneumatized portions of the temporal bone, lined by keratinized, stratified squamous epithelium and containing desquamated epithelium and/or keratin. Acquired, as distinct from congenital, cholesteatoma most often develops as a complication of long-standing chronic OM. However, the condition also may develop from a

deep retraction pocket of the tympanic membrane or as a consequence of epithelial implantation in the middle-ear cavity from traumatic perforation of the tympanic membrane or insertion of a tympanostomy tube. Cholesteatomas tend to expand progressively, causing bony resorption, and may extend intracranially, with potentially life-threatening consequences. Cholesteatoma should be suspected if otoscopy shows a discrete, whitish opacity of the eardrum or a polyp protruding through a defect in the eardrum; or white caseous debris persistently overlies the eardrum, especially its superior portion; or persistent malodorous aural discharge is present. When cholesteatoma is suspected, consultation with an otolaryngologist should be sought immediately. Delayed recognition and treatment can have significant long-term consequences, including the need for more extensive surgical treatment, permanent hearing loss, facial nerve injury, labyrinthine damage with loss of balance function, and intracranial extension. Tympanomastoid surgery is required for treatment of cholesteatoma.

Labyrinthitis

Labyrinthitis occurs uncommonly as a result of the spread of infection from the middle-ear and/or mastoid to the inner-ear. Cholesteatoma or chronic suppurative OM is the usual source. Symptoms and signs include vertigo, tinnitus, nausea, vomiting, hearing loss, nystagmus, and clumsiness. Treatment is directed at the underlying condition and must be undertaken promptly to preserve inner-ear function and prevent the spread of infection.

Intracranial Complications

Meningitis, epidural abscess, subdural abscess, focal encephalitis, brain abscess, lateral sinus thrombosis (also called sigmoid sinus thrombosis), and otitic hydrocephalus each may develop as a complication of acute or chronic middle-ear or mastoid infection, through direct extension, hematogenous spread, or thrombophlebitis. Bony destruction adjacent to the dura often is involved, and a cholesteatoma may be present. In a child with middle-ear or mastoid infection, the presence of any systemic symptom, such as fever, headache, or lethargy, of extreme degree, or a finding of meningismus or of any central nervous system sign on physical examination should prompt suspicion of an intracranial complication.

When an intracranial complication is suspected, lumbar puncture should be performed only after imaging studies establish that there is no evidence of mass effect or hydrocephalus. In addition to examination of the cerebrospinal fluid, culture of middle-ear exudate obtained via tympanocentesis may identify the causative organism, thereby helping guide the choice of antimicrobial drugs, and myringotomy should be performed to permit middle-ear drainage.

Intravenous antibiotic treatment of all intracranial complications, including surgical drainage of any abscess, is required urgently. If mastoiditis is present, mastoidectomy should be undertaken as soon as feasible. When meningitis develops as a complication of AOM, investigation should be directed at the possible presence of a perilymphatic fistula.

Lateral sinus thrombosis may be complicated by dissemination of infected thrombi with resultant development of septic infarcts in various organs. Diagnosis is facilitated through MRI. Mastoidectomy may be required even in the absence of osteitis or coalescent mastoiditis, especially in the case of propagation or embolization of infected thrombi. However, mastoiditis sometimes can be treated with tympanostomy tube placement and intravenous antibiotics. Anticoagulation therapy also may be considered in the treatment of lateral sinus thrombosis; however, an otolaryngologist should be consulted before initiating this therapy to coordinate the possible need for surgical intervention prior to anticoagulation.

Otitic hydrocephalus, also termed *benign intracranial hypertension* (pseudotumor cerebri), is an uncommon condition that consists of increased intracranial pressure without dilatation of the cerebral ventricles, occurring in association with acute or chronic OM or mastoiditis. The pathogenesis is uncertain, but the condition commonly is associated with lateral sinus thrombosis, and the pathophysiology may involve obstruction by thrombus of intracranial venous drainage into the neck, producing a rise in cerebral venous pressure and a consequent increase in cerebrospinal fluid pressure. Symptoms are those related to increased intracranial pressure. Signs may include, in addition to evidence of OM, paralysis of 1 or both lateral rectus muscles and papilledema. MRI can confirm the diagnosis. Treatment measures include the use of antimicrobials and drugs such as acetazolamide or furosemide to reduce intracranial pressure, mastoidectomy, repeated lumbar puncture, lumboperitoneal shunt, and ventriculoperitoneal shunt. If left untreated, otitic hydrocephalus may result in loss of vision secondary to optic atrophy.

Physical Sequel

The physical sequel of OM consists of structural middle-ear abnormalities resulting from long-standing middle-ear inflammation. In most instances, these sequel are consequence of severe and/or chronic infection, but some also may result from the presumably noninfective inflammation of long-standing OME. The various sequel may occur singly, or inter relatedly in various combinations.

Tympanosclerosis consists of whitish plaques in the tympanic membrane and nodular deposits in the submucosal layers of the middle ear. The changes involve hyalinization with deposition of calcium and phosphate crystals. There may be associated conductive hearing loss, but this

is uncommon. In developed countries, probably the most common cause of tympanosclerosis is tympanostomy tube insertion.

Atelectasis of the tympanic membrane is a descriptive term applied to either severe retraction of the tympanic membrane caused by high negative middle-ear pressure or loss of stiffness and medial prolapse of the membrane, presumably as a consequence of long-standing retraction or severe or chronic inflammation. A retraction pocket is a localized area of atelectasis. Atelectasis often is transient and usually is not accompanied by symptoms, but a deep retraction pocket may lead to erosion of the ossicles and adhesive otitis, and may serve as the nidus of a cholesteatoma. For a deep retraction pocket, and for the unusual instance in which atelectasis is accompanied by symptoms such as otalgia, tinnitus, or conductive hearing loss, tympanostomy tube insertion is necessary.

Adhesive OM consists of proliferation of fibrous tissue in the middle-ear mucosa, which may in turn result in impaired movement of the ossicles, rarefying osteitis and ossicular discontinuity, conductive hearing loss, and cholesteatoma. The hearing loss may be amenable to surgical correction.

Cholesterol granuloma is an uncommon condition in which the tympanic membrane appears to be dark blue, reflecting the presence of thick, granulomatous material in the middle-ear cavity. The condition appears to result more often from long-standing OME than from frank middle-ear infection. Tympanostomy tube insertion alone does not provide satisfactory relief, and the required treatment is middle-ear and mastoid surgery.

Chronic perforation may develop after spontaneous rupture of the tympanic membrane during an episode of AOM, as sequel of chronic suppurative OM, from trauma, or as a result of failure of closure of the tympanic membrane following extrusion of a tympanostomy tube. A chronic perforation almost always is amenable to surgical repair, usually after the child has been free of OM for an extended period.

Permanent *conductive hearing loss* may result from any of the conditions just described. Rarely, permanent sensorineural hearing loss may occur in association with acute or chronic OM, presumably from the spread of infection or products of inflammation through the round window membrane, or as a consequence of suppurative labyrinthitis.

POSSIBLE DEVELOPMENTAL SEQUEL

Permanent hearing loss in children has a significant negative impact on development, particularly delays in speech and language. The degree to which OM impacts long-term development in children is difficult to assess, and there have been conflicting studies examining this question. However, the developmental impact is most likely to

be significant in children with greater levels of hearing loss, hearing loss that is sustained for longer periods of time, and hearing loss that is bilateral, and in those children who have other developmental difficulties or risk factors for developmental delay.

Prevention

- Encouraging breast-feeding
- Feeding child upright if bottle fed
- Avoiding exposure to passive smoke
- Tobacco cessation counseling
- Limiting exposure to numbers of children to the extent possible
- Teaching adults and children careful hand washing technique
- Limiting exposure to viral upper respiratory infections
- Avoid pacifier use beyond 10 months of age
- Ensure immunizations are up-to-date; including influenza and 13 valent conjugated polysaccharide vaccine (PCV13).

SUMMARY

This clinical practice guideline provides evidence-based recommendations for the definition and management of AOM in children from 2 months through 12 years of age without signs or symptoms of systemic illness unrelated to the middle-ear. It emphasizes accurate diagnosis and adherence to a consistent definition of AOM. Management of the pain associated with AOM is identified as an essential aspect of care. An option to observe a select group of children with AOM with symptomatic therapy for 48 to 72 hours is supported by evidence and may potentially lead to decreased use of antibacterial agents. If a decision is made to treat with an antibacterial agent, amoxicillin at a dose of 80 to 90 mg/kg per day is recommended as the initial antibacterial agent of choice for most children. Additional guidance is given for choosing an antibacterial agent when an alternative to amoxicillin is indicated. Also addressed is evidence related to the prevention of AOM and the role of CAM in the treatment of AOM. The recommendations are summarized.

Assessment of Critically Ill Child in the PICU

Kundan Mittal

AIM

The aim of initial assessment of critically ill patient is to identify physiological abnormalities, appropriate measures to correct these physiological abnormalities, and to diagnose the underlying etiology of the critical illness. Both acute illness and injury result in alteration in nearly all bodily physiological system (altered vital parameters, immunity response, coagulation system, metabolism of glucose, fat and protein, and psychological response). Prompt and early recognition of these altered physiological parameters in critically ill will make it easier for the physician to manage the child with simple interventions and prevent further harm. Children may not show signs and symptoms of acute illness at early stage due to their greater tendency to compensate.

Children are different anatomically, physiologically and developmentally from adults and their psychomotor skills and social skills depend on the developmental stage of life. The appearance and expected behavior to illnesses also varies with age. Despite having similar genetic make-up their expressions are different from adults. Children also have certain anatomical and physiological differences from adults. Moreover, children depend on care-givers for their needs. It is also important to know weight and height of different age group.

- Age distribution
 - Newborn: From birth to 28 days
 - Infant: up to one year
 - Toddler: 1 to 3 years
 - Preschool: 3 to 6 years
 - School age child: 6 to 12 years
 - Adolescent: 12 to 18 years
- Calculation of weight
 - 1 to 6 years = $\text{Age} \times 2 + 8$
 - 7 to 12 years = $\text{Age} \times 7 - 5/2$

- Calculation of height (2-12 years)
- $\text{Age in year} \times 6 + 77 = \text{cm}$

Initial or general assessment of acutely ill child helps to evaluate physiological abnormality, severity of illness and stabilization of child. Systematic approach has been developed for the assessment of critically ill. There are four components for assessment:

- General assessment
- Primary assessment
- Secondary assessment
- Tertiary assessment

The routine systematic approach of taking full history, conducting complete physical examination and investigation, making correct diagnosis and planning treatment cannot be followed in emergency situation. “*Time is of essence*” In assessing critically ill, all the above steps should be carried simultaneously, i.e. in parallel. The best guess diagnosis should be made and patient should be reassessed after every intervention. In acute illness, we should restrict ourselves only to the information required for immediate intervention rather eliciting detailed history. Background health information/status and hospital record/charts/information from paramedics are also necessary in many situations especially in ICU. Assessment may also be required for specific situations like nutritional assessment, preoperative or postoperative assessment, neurological assessment, organ transplant decision, during transport, DNAR and brain death issues. We will primarily focus on our assessment in critically ill who are first seen or encountered in ICU. Sequence assessment is same in whatever conditions we are assessing the critically ill child. Various conditions requiring immediate assessment in ICU’s are given below (Table 1).

Quick assessment is done using pediatric assessment triangle (Fig. 1) to know whether child is stable or severely ill. Accordingly child is stated to be having either

Table 1: Conditions requiring immediate assessment in ICU

System(s)	Clinical features
Cardiovascular system	Supraventricular tachycardia, symptomatic bradycardia, tension pneumothorax, severe hypotension
Respiratory system	Tachypnea, increased work of breathing, bradypnea, oxygen saturation <94% in room air, asynchrony with ventilator, cyanosis
Nervous system	Acute deterioration in consciousness level, agitation, aggressive behavior, seizures
Renal	Decreased urine output <0.5 ml/kg/hr over a period of 6 hrs
Gastrointestinal system	Hematemesis (bleeding from upper gut), severe jaundice, melena (black color stool)
Metabolic	Metabolic acidosis, symptomatic hypoglycemia (low blood sugar), electrolyte disturbances

life-threatening problem where immediate resuscitation is started using BLS/PALS guidelines or categorized according to illness (respiratory and or cardiovascular). Neurological disorders can be primary or secondary to hypoperfusion or hypoxemia. PAT is a rapid way to assess physiological abnormalities by visual and auditory clues within few seconds. The three components of pediatric assessment triangle (appearance, work of breathing, and circulation to skin) are interdependent and reflect child's physiological status. The three components of the PAT reflects general status, oxygenation and ventilation status, perfusion, and brain functions of the child.

COMPONENTS OF PEDIATRIC ASSESSMENT TRIANGLE

- *Appearance:* It reflects the adequacy of ventilation, oxygenation, brain perfusion, homeostasis, and brain

**Fig. 1:** Pediatric assessment triangle

functions. Remember that appearance does not reflect etiology of disease. Various components of appearance are tone, interactiveness, consolability, gaze, speech and cry.

- *Work of breathing:* It primarily reflects oxygenation and ventilation status of the child. Visual and auditory clues for increased work of breathing are; *abnormal sounds, head bobbing, abnormal position, retractions, nasal flaring, and tachypnea.*
- *Circulation:* Aim is to assess the adequacy of cardiac output and perfusion of vital organs. Pallor, mottling, abnormal behaviour, tachypnea and cyanosis are features of inadequate circulation. Also see exposed part of body for any injury and evidence bleed.

Three components when combined can give an idea of likelihood physiological abnormalities, severity of illness, and define life threatening conditions (Tables 2 to 4). This also gives an idea that how quickly one should intervene and what type of management to be instituted.

Once the general assessment has been done, life-threatening problem has been dealt then secondary and tertiary assessment is done. In the mean while, child is also attached to monitor. The primary assessment includes assessment of airway, breathing, circulation, disability, and exposure or environment. The problem identified should be classified according to type and severity and interventions are done accordingly to stabilize the child. One may take the appropriate blood samples simultaneously.

Table 2: Categorization of severity of illness using PAT

Appearance	Work of breathing	Circulation	Physiological status
Abnormal	Normal	Normal	Primary brain dysfunction
Normal	Abnormal	Normal	Respiratory distress
Abnormal	Abnormal	Normal	Respiratory failure
Normal	Normal	Abnormal	Compensated shock
Abnormal	Normal	Abnormal	Hypotensive shock
Abnormal	Abnormal	Abnormal	Cardiorespiratory failure

Table 3: Categorization of patients after initial assessment

1. Stable: These patients need minimal monitoring and have no abnormality in appearance (level of consciousness), work of breathing and circulation to skin
2. Stable with risk of deterioration
3. Respiratory distress/failure
4. Cardiovascular compromise
5. Neurological compromise
6. Cardiopulmonary failure/arrest

Table 4: Life-threatening conditions required immediate attention

1. Complete or partial airway obstruction
2. Apnea, bradypnea, tachypnea, increased work of breathing
3. Signs of poor perfusion, symptomatic bradycardia, hypotension, tachycardia, ventricular fibrillation or tachycardia, supraventricular tachycardia, symptomatic complete heart block
4. Unresponsiveness, decreased response or abnormal motor response to pain
5. Hypothermia, bleeding consistent with septic shock, acute abdominal distension
6. In PICU child fighting with ventilator, acute fall in oxygen saturation, ET blockade, status epilepticus, coning of brain

Secondary assessment done includes SAMPLE history and focussed examination including vital parameters. After you have detected the problem, the ancillary studies are carried out according to system. Blood sugar and arterial

blood gas analysis are two most important investigations to be carried out in ICU and emergency. The important physiological parameters of clinical significance are given in Tables 5 to 7.

Table 5: Normal respiratory rate in children

Age	Breaths/min
Infant (<1 year)	30–60
Toddler (1–3 years)	24–40
Preschool (4–5 years)	22–34
School age (6–12 year)	18–30
Adolescent (13–18 year)	12–16

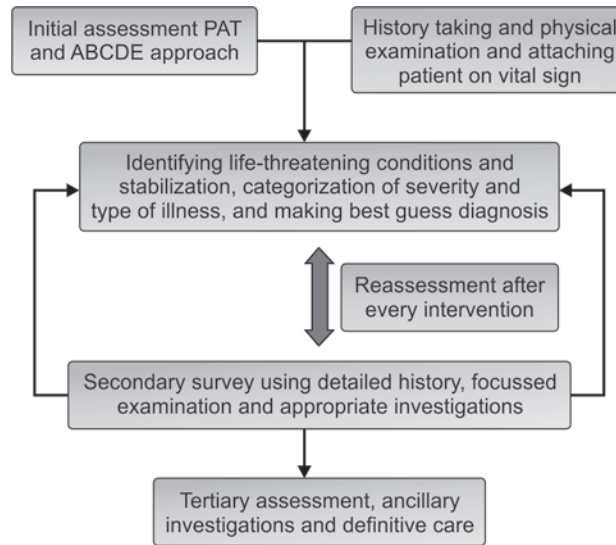

Table 6: Normal heart rate in children

Age	Awake	Mean	Sleeping
Newborn to 3 months	85–205	140	80–160
3 months to 2 year	100–190	130	75–160
2 years to 10 years	60–140	80	60–90
> 10 years	60–100	75	50–90

Table 7: Normal blood pressure in children

Age	SBP (mm Hg)		DBP (mm Hg)	
	Female	Male	Female	Male
Neonate (1st day)	60–76	60–74	31–45	30–44
Neonate (4th day)	67–83	68–84	37–53	35–53
Infant (1 month)	73–91	74–94	36–56	37–55
Infant (3 months)	78–100	81–103	44–64	45–65
Infant (6 months)	82–102	87–105	46–66	48–68
Infant (1 year)	68–104	67–103	22–60	20–58
Child (2 years)	71–105	70–106	27–65	25–63
Child (7 years)	79–113	79–115	49–77	38–77
Adolescent (15 years)	93–127	95–131	47–85	45–85
Mean blood pressure = $55 + (\text{age in years} \times 1.5)$ mm Hg				

SUMMARY OF ASSESSMENT OF ACUTELY/CRITICALLY ILL

Section 6

Neurology

Editors
RK Sabharwal
Nandan Yardi

*Ravindra Arya, Puneet Jain***STORY**

The story of development of drug therapy for epilepsy has all the ingredients of romantic fiction: mystery, jealousy, serendipity and genuine hard work. In May 1857, Dr Edward Sieveking presented before Royal Medical and Chirurgical Society an 'analysis of 52 cases of epilepsy'. During discussion, Sir Charles Locock, obstetrician to Queen Victoria, shared his experience with potassium bromide in young women with 'hysterical epilepsy connected with the menstrual period'; and, thus, began the pharmacotherapy of epilepsy. The story moves from Victorian academics to a young resident psychiatrist, Alfred Hauptmann, who lived above an epilepsy ward and was frequently woken up when these patients kept falling out of bed during their seizures. To ensure a good night's sleep, he tried sedating these patients with phenobarbital and noticed that not only they had fewer seizures in night, but they did have reduced seizures the next day also. He recorded and published his observations and the modern drug therapy of epilepsy started. The next breakthrough came with the development of a feline model of epilepsy by Tracy Putnam and Fredric Gibbs; supply of non-sedative phenyl compounds by a pharmaceutical company and clinical testing of the relatively non-toxic one (phenytoin) by Houston Merritt. In the mid-1960s, a pharmaceutical company tried to develop a competitor for recently marketed chlorpromazine and thus came the carbamazepine. Simultaneously in 1963, Pierre Eymard realized that valproic acid, which he was using for dissolving his insoluble khallins, was probably the active ingredient and not the solutes, all of which surprisingly acquired anti-seizure property. Concurrently, Leo Sternbach developed benzodiazepines and their clinical use was pioneered by Henri Gastaut with the seminal paper on the use of diazepam for the treatment of status epilepticus in 1965. In 1975, National Institute of Neurological Disorders and Stroke

established the Anticonvulsant Drug Development program which resulted in screening of >28,000 chemical compounds. Emphasis on target-oriented design, structural modification of existing chemical compounds and development of rodent seizure models has resulted in licensure and clinical use of several 'newer' antiepileptic drugs (AEDs) in last 4 decades, many of which have truly novel mechanisms and have contributed to increasing understanding of neurochemistry.

NEWER ANTIEPILEPTIC DRUGS**Gabapentin**

Gabapentin (GBP) is a structural but not functional analogue of γ -amino-butyric acid (GABA). It neither interacts with GABA receptors nor affects GABA reuptake, synthesis or metabolism. GBP binds to $\alpha 2$ - δ subunit of L (large conductance) type voltage-gated calcium channels, leading to reduced transmitter release and attenuation of post-synaptic excitability. The oral bioavailability of GBP varies inversely with dose. It is excreted unchanged in urine.

It is licensed for adjunctive treatment of partial seizures with or without secondary generalization in patients 6 years or older. Clinically, GBP is a narrow spectrum AED with poor efficacy and seldom offers substantial therapeutic benefit. There is risk of exacerbation of generalized seizures and caution must be exercised when using it in patients with mixed seizure types.

Overall, GBP has low prevalence of adverse effects. Behavioral manifestations are common including emotional lability, aggressiveness, hostility, hyperactivity and attention deficit. Other reported adverse effects are fatigue, somnolence, nausea, dyspepsia, rash and weight gain. GBP is initiated at 15 to 20 mg/kg/day in 3 divided doses and up-titrated to a usual maintenance dose of 35 to 40 mg/kg/day (maximum 3600 mg/day).

Lacosamide

Lacosamide (LAC) was licensed for clinical use in 2008. It acts by enhancing slow inactivation of voltage-gated sodium channels resulting in stabilization of hyperexcitable neuronal membranes. It is unique in this regard, since other sodium channel blockers modulate fast inactivation. It is known to bind to collapsing response mediator protein-2, a phosphoprotein involved in neuronal differentiation and control of axonal outgrowth. This action is supposedly neuroprotective; however, its relevance to antiseizure efficacy is undefined. It has 100 percent oral bioavailability unaffected by food co-ingestion, with <15 percent plasma protein binding. It is metabolized in liver, 30 percent by demethylation to inactive metabolites. Forty percent of administered dose is excreted unchanged in urine.

LAC is licensed for adjunctive treatment of partial onset seizures with or without secondary generalization in patients 17 years and older. Since an intravenous formulation is available, it has also been used for non-convulsive status epilepticus.

Common adverse effects involve nervous system particularly the vestibulo-cerebellar structures: dizziness, vertigo, balance and coordination difficulties, memory impairment, somnolence, tremor, nystagmus, diplopia, blurred vision, headache, nausea, vomiting, and depression. Hence, patients should be warned against increased risk of accidental injury or falls. Other adverse effects include constipation, flatulence, and pruritus. LAC is known to increase PR interval, therefore, patients with known second- or third-degree atrioventricular block may be at risk of myocardial infarction or heart failure. Also, caution should be exercised when co-prescribing with other AED known to prolong PR interval, e.g. carbamazepine, lamotrigine, and pregabalin.

LAC is usually initiated at 50 mg twice daily for 1 week, increasing by 100 mg/day in 2 divided doses at weekly intervals to a maximum of 400 mg/day. Intravenous solution (10 mg/ml) is bioequivalent and hence infused in same doses over 15 to 30 minutes. Optimal therapeutic plasma levels have been determined to be 10 to 20 mg/L (40–80 $\mu\text{mol/L}$). Interestingly, LAC can be monitored using salivary level which represent the free non-protein bound plasma concentration and is pharmacologically relevant. The syrup formulation of LAC contains fructose and aspartame, contraindicating it for patients with hereditary fructose intolerance and phenylketonuria respectively. LAC requires dose modification in patients with renal impairment with a total maximum dose of 250 mg/day in patients with creatinine clearance <30 ml/min.

Lamotrigine

Lamotrigine (LTG) inhibits voltage gated sodium channels in a voltage-, frequency- and use-dependent manner

by interacting with open conformation of the channels at α -pore forming subunit. It is also known to inhibit release of glutamate and increase the activity of dendritic hyperpolarization activated cation channels, increasing the excitatory threshold. LTG has a high oral bioavailability (~98%) with roughly 50 percent plasma protein binding. It is glucuronized to inactive metabolites which are eliminated in urine along with some unchanged dose. LTG is the only newer AED to show auto-induction of its metabolism. It has a long $t_{1/2}$ - β (~30 hours) which can double with valproate co-therapy.

LTG is approved monotherapy in patients aged >12 years for treatment of partial seizures and primary or secondarily generalized tonic-clonic seizures; as adjunctive therapy for the same indication in patients aged 2 to 12 years; and, adjunctive therapy of LGS in patients 2 years or older. It is also used for treatment of absence seizures where valproate and/or ethosuximide have failed. LTG is known to exacerbate myoclonic seizures in JME, Dravet syndrome or progressive myoclonus epilepsy. Children with cryptogenic perisylvian epilepsy have been reported to develop negative myoclonus, atypical absence or electrical status epilepticus with LTG. Some of these cases probably represent atypical benign partial epilepsy or pseudo-Lennox syndrome (personal experience).

The major adverse effect with LTG is the erythematous rash appearing 2 to 8 weeks after initiation of therapy. There is a huge variation in the reported incidence of LTG-induced rash (0.5-10%). Our viewpoint is that the incidence of rash does not differ significantly from conventional AED like carbamazepine, but, a disproportionately higher proportion of patients develop toxic epidermal necrolysis or Stevens-Johnson syndrome. Higher doses, rapid titration and concomitant valproate use increases the risk. Clinically, any child on LTG who develops a rash should be promptly evaluated. Other adverse effects include somnolence, headache, diplopia, ataxia, increased appetite, anxiety, tics and tremors. Clinically, most relevant drug interaction of LTG is with valproate which inhibits its metabolism and decreases its clearance. LTG is prescribed in 2 divided doses as per the schedule given in Table 1.

Levetiracetam

Levetiracetam (LEV) has a unique antiepileptic mechanism. It binds to a specific synaptic vesicle protein (SV2A) which is probably involved in the vesicle fusion and exocytosis, thus affecting release of multiple neurotransmitters. Other postulated mechanisms include partial inhibition of N (neuronal) type voltage gated calcium channels, reduction of GABA and glycine mediated inhibition; and, decreased voltage-gated potassium currents. LEV has high oral bioavailability (>95%) unaffected by food and low protein binding (<10%). It has minimal hepatic metabolism and primarily renal excretion.

Table 1: Dosing schedule for lamotrigine

	<i>Monotherapy</i>	<i>With enzyme inducers</i>	<i>With valproate</i>
Initiation	0.3 mg/kg/day	0.6 mg/kg/day	0.15 mg/kg/day
Increment (1-2 weekly)	0.3 mg/kg/day	0.6 mg/kg/day	0.15 mg/kg/day
Maintenance	2-8 mg/kg/day	5-15 mg/kg/day	1-5 mg/kg/day
Maximum dose	400 mg/day	800 mg/day	200 mg/day

LEV has a fairly broad range of efficacy and represents a first or second choice for idiopathic generalized epilepsies (IGE) with primary generalized or myoclonic seizures; and, for partial seizures with or without secondary generalization where it is the main challenger for carbamazepine. It is approved for use in partial seizures (+/- secondary generalization) as monotherapy in patients 16 years or older and as adjunct in those 4 years and above. It is also licensed for adjunctive treatment of myoclonic seizures in patients 12 years or older with juvenile myoclonic epilepsy (JME); and, of primary generalized tonic-clonic seizures (GTCS) in patients above 6 years with idiopathic generalized epilepsy; where it is a contender of valproate. Other indications include absence seizures, benign rolandic epilepsy, post-anoxic myoclonus, progressive myoclonic epilepsy (Unverricht-Lundborg syndrome), and, severe polymorphic epilepsy of infancy (Dravet syndrome).

Adverse effects are infrequent and usually include somnolence, asthenia, dizziness and headache. Behavioral effects like aggression, emotional lability or oppositional tendency is particularly problematic in children.

The initial oral dose is 10 mg/kg/day with bi-weekly increases of 20 mg/kg/day to the maximum maintenance dose of 60 mg/kg/day. The maximum dose is 3000 mg/d. In children, it is prescribed in 3 divided doses. Optimal therapeutic plasma concentration is 12 to 46 mg/L (70–270 µmol/L). For status epilepticus, the loading dose is 20 mg/kg infused over 15 to 20 minutes. Repeat mini-bolus with 10 mg/kg may be followed by usual maintenance dose.

Brivaracetam is the S enantiomer of LEV with 13-fold higher binding affinity for SV2A. It is expected to share broad antiepileptic efficacy and has shown increased potency than LEV against secondarily generalized seizures, in preclinical efficacy. It is likely to have more favorable adverse effect profile in children.

Rufinamide

Rufinamide (RUF) acts on inactivated voltage-sensitive sodium channels and blocks their return to activated state thereby preventing the generation of sustained bursts of high frequency action potentials. Its oral bioavailability has not been determined but probably varies inversely with dose, having nonlinear pharmacokinetics at a dose >1600 mg/day. More importantly, food co-ingestion substantially increases the rate and extent of absorption. It is 35 percent protein bound in plasma. RUF is metabolized

primarily by CYP independent hydrolysis. The resulting inactive metabolite is primarily excreted in urine along with a minor acyl-glucuronide.

RUF is licensed for adjunctive treatment of Lennox-Gastaut syndrome (LGS) in patients 4 years and older. It is efficacious against multiple seizure types in LGS.

Common adverse effects include dizziness, diplopia, somnolence, nausea, vomiting and fatigue. It is known to decrease QTc interval. Hence, it should be avoided in patients with congenital short QT syndrome or a family history of such disorder. There are reports of increased frequency of status epilepticus in patients on RUF, but the significance of this phenomenon in clinical decision-making requires further data. Conventional enzyme inducers and vigabatrin are known to decrease the plasma level of RUF, whereas, valproate can increase it. On the other hand, RUF can increase plasma levels of carbamazepine and lamotrigine; and, decrease those of phenytoin, phenobarbital and triazolam. Also, RUF enhances the metabolism of hormonal contraceptives, leading to reduced efficacy and breakthrough bleeding.

For children 4 years or older, weighing <30 kg and not receiving valproate, RUF is started at 100 mg/day increasing every 2 to 3 days by 200 mg/day to a usual maintenance dose of 1000 mg/day. If the child is on valproate, the dosing schedule remains the same but the typical maintenance dose is decreased to 400-600 mg/day. For adults and children >30 kg, treatment is started at 200 mg/day with every 2 day increase by 400 mg/day to a usual maintenance dose of 1800 mg/day (30-50 kg), 2400 mg/day (50-70 kg) and 3200 mg/day (>70 kg) respectively. It is prescribed in 2 daily divided doses, along with food. It is advisable to obtain liver and renal function tests and electrocardiogram before starting and yearly during treatment. Therapeutic plasma concentrations are determined to be 10-25 mg/L (42-105 µmol/L). The commercial formulation of RUF contains lactose; hence it should be avoided in patients with lactose intolerance.

Stiripentol

Stiripentol (STP) increases GABA levels in the nervous system by inhibition of synaptic uptake and inhibition of GABA-transaminase. It also enhances GABA-A receptor-mediated transmission and increases the mean-duration (but not the frequency) of GABA-A receptor chloride channels by a barbiturate-like mechanism. STP has significant

(99%) plasma protein binding. It is metabolized in the liver, primarily by desmethylation and glucuronidation, mediated by CYP1A2, CYP2C19, and CYP3A4, to 13 different inactive metabolites. It has a saturable kinetics with elimination half-life and clearance inversely varying with dose. About 73 percent of an administered dose is excreted in urine as metabolites.

It has been authorized under a “conditional approval” scheme by the European Medicines Agency for adjunctive treatment of seizures in children with severe polymorphic epilepsy of infancy (Dravet syndrome). However, it has also been used as adjunctive treatment with carbamazepine in children with refractory focal seizures. Importantly, carbamazepine, phenytoin and phenobarbital should not be combined with STP in the management of Dravet syndrome.

Common adverse effects include mild-moderate gastrointestinal symptoms: anorexia, loss of appetite, nausea or vomiting. Weight gain is common when it is co-administered with valproate. Less commonly STP causes drowsiness, ataxia, hypotonia, dystonia, hyperkinesias insomnia, aggressiveness, irritability, or hyperexcitability. Rarely, cutaneous photosensitivity has been reported.

STP is known to have numerous drug interactions. Conventional enzyme inducers are known to decrease plasma levels of STP. Contrarily, STP is a potent inhibitor of CYP2C19, CYP3A4, and CYP2D6; and, increases plasma levels of carbamazepine, phenobarbital, valproic acid, clobazam and its pharmacologically active metabolite N-desmethyloclobazam; and, numerous other drugs viz. citalopram, omeprazole [CYP2C19]; astemizole, chlorpheniramine, calcium channel blockers, statins, codeine [CYP3A4]; propranolol, fluoxetine, sertraline, haloperidol, and tramadol [CYP2D6]. Because of this interaction STP enhances anorexia associated with valproic acid; risk of polymorphic ventricular tachyarrhythmia with cisapride, halofantrine, pimozide, quinidine, and bepridil; risk of extremity necrosis with ergot alkaloids; nephrotoxicity with tacrolimus, sirolimus and cyclosporine; and, rhabdomyolysis with statins.

It is usually initiated at a dose of 50 mg/kg/day in 2 to 3 divided doses, increasing every 3 days by 100 mg/kg/day to a maximum of 4 g/day. Clinically, the regimen would almost always include a co-prescription of valproate and clobazam; hence, upward titration should be cautious once the dose exceeds 3 g/day. Weight gain becomes an important issue with this regimen, so, it is good to obtain baseline fasting blood glucose and serum lipids (personal practice). STP is rapidly degraded by gastric acid, hence, it must always be ingested with food, but co-ingestion of milk or dairy products and carbonated drinks should be avoided. It should be remembered that STP was evaluated for the treatment of Dravet syndrome in children >3 years or age. Thus, the decision to prescribe it to younger children should be made on an individual basis.

Topiramate

Topiramate (TPM) is a sulfamate-substituted monosaccharide derivative of D-enantiomer of fructose. The proposed mechanisms for TPM include inhibition of AMPA or kainate subtype of glutamate receptors, augmentation of GABA-A receptor mediated chloride currents, inhibition of sodium and L (large conductance) type voltage gated calcium channels, increased potassium channel conductance and weak carbonic anhydrase inhibition. It has high oral bioavailability (80%) and the absorption is not significantly affected by food. It has minimal liver metabolism and mainly renal excretion.

It is approved as monotherapy (age >10 years) or adjunctive therapy (age >2 years) of partial seizures with or without secondary generalization; and, for adjunctive therapy of seizures associated with LGS (age >2 years). Other indications include absence seizures, infantile spasms, JME, and, myoclonic-astatic epilepsy (MAE, Doose syndrome). Clinically, it is mostly used as add-on in patients with focal epilepsy failing adequate monotherapy and in children with LGS.

Adverse effects commonly affect cognition and include impaired expressive language function, impaired verbal memory, dysnomia and decline in word fluency. Other adverse effects include somnolence, fatigue, ataxia, angle closure glaucoma, weight loss, metabolic acidosis, renal stones, hypohidrosis and paresthesias. Higher dose, rapid titration and poly-therapy contribute to increased propensity for adverse effects. Children on ketogenic diet should specially be monitored for metabolic acidosis and nephrolithiasis. Concurrent administration with valproate is known to increase the risk of hyperammonemic encephalopathy and such children should be screened for inborn urea cycle disorders.

TPM is started at 0.5 to 1 mg/kg/day with slow titration to usual maintenance dose of 5 to 9 mg/kg/day (maximum 500 mg/d), given in 2 divided doses. Renal impairment with creatinine clearance <70 ml/min/1.73 m² warrants dose adjustment. There is a report of using TPM for refractory status epilepticus with nasogastric bolus dose of 10 mg/kg for 2 days followed by 5 mg/kg/day.

Vigabatrin

Vigabatrin (VGB) exists as a racemic mixture with both an active S(+) enantiomer and inactive R(-) enantiomer. It is an irreversible inhibitor of GABA-transaminase, the major GABA degradation enzyme. Hence, the pharmacologic action of VGB lasts typically for 4 to 6 days, until inactivated enzymes are re-synthesized. It may also stimulate GABA release. It has good oral bioavailability (>90%), negligible protein binding and minimal liver metabolism. Renal excretion of unchanged drug is the major route of elimination.

VGB is the drug-of-choice for treatment of infantile spasms associated with tuberous sclerosis complex. It is licensed for monotherapy of other cryptogenic infantile spasms and for adjunctive therapy of resistant focal epilepsy. Clinically, VGB is also used as first or second line treatment of symptomatic infantile spasms. Importantly, VGB can aggravate atypical absence seizures in LGS where it can provoke absence status epilepticus; and, myoclonic seizures in static encephalopathy and progressive myoclonus epilepsy syndromes.

The major adverse effect of VGB is irreversible visual field constriction which starts as a bilateral nasal defect and may progress to a bilateral concentric field defect. The central visual acuity and color vision are always preserved. It is recommended that patients should undergo testing at treatment initiation, then at 3-month intervals for the first 18 months of treatment, and every 6 months thereafter. Static or kinetic perimetry is suitable for patients aged >9 years of age. Field-specific visual evoked potentials are sensitive and specific for identifying the VGB-induced defect in children aged >2 years. Full-field or multifocal electroretinogram may be useful to evaluate infants and developmentally delayed children. The next common group of adverse effects includes behavioral changes: hyperactivity, irritability, aggression, self-injurious behavior and self-defiance. Other reported undesirable effects are weight gain, facial edema, headache, insomnia, ataxia, tremor, somnolence and stupor. VGB does not have significant drug interactions except that it may decrease phenytoin levels. The recommended dose of VGB is 20-150 mg/kg/day in 2 divided doses (maximum 3000 mg/day).

Zonisamide

Zonisamide (ZNS) is a sulfonamide with several proposed mechanisms including partial blockade of activity-dependent sodium channels, blockade of the T (transient opening)-type voltage gated calcium channels, and, inhibition of potassium-mediated glutamate release. It has other molecular effects whose relevance to antiseizure efficacy is not exactly defined, including, increase in extracellular levels of dopamine and serotonin, upregulation of excitatory amino acid carrier-1, downregulation of the expression of GABA transporter-1, and weak carbonic anhydrase inhibition.

It has >90 percent bioavailability after oral administration. Co-ingestion of food may delay but does not decrease the absorption. It is metabolized by successive acetylation, reduction and glucuronidation, the intermediate step being mediated by CYP3A4 iso-enzyme. The metabolites are not pharmacologically active. It excreted by kidney, 35 percent unchanged and 65 percent as metabolites. At a creatinine clearance of <20 ml/min, the clearance of ZNS is reduced by 35 percent. Hence, it requires a proportional dose modification in patients with renal compromise.

ZNS is licensed for adjunctive therapy for partial and secondarily generalized seizures in adults. However, it is a broad spectrum AED with efficacy in several seizure types and epilepsy syndromes including childhood onset focal seizures with or without secondary generalization, absence seizures, infantile spasms and myoclonic seizures occurring in the context of JME, LGS, MAE (Doose syndrome) and some progressive myoclonus epilepsy syndromes.

Common adverse effects include neuropsychiatric symptoms like drowsiness, fatigue, ataxia, reduced spontaneity and psychomotor slowing or transient impairment in verbal learning. Contrarily, sometimes there may be aggression, agitation, irritability, poor attention, hyperactivity, dysphoria, paranoia or even frank psychosis. The next common adverse events involve gastrointestinal system, e.g. anorexia, nausea, abdominal discomfort, vomiting and weight loss. Although ZNS is chemically similar to sulfonamide antibiotics, it does not contain an arylamine group at N4 position, hence, the risk of allergic reactions is substantially lower. Less commonly, metabolic and autonomic adverse effects have been reported including metabolic acidosis, nephrolithiasis, paresthesias and hypohidrosis. Because of 65 percent hepatic metabolism it is susceptible to a decrease in plasma levels when administered concurrently with cytochrome inducers. Risperidone is also known to decrease plasma levels, however, the mechanism is not known.

Children are typically started on 1 to 2 mg/kg/day with upward titration every 1 to 2 weeks to a usual maintenance dose of 8 mg/kg/day. If concurrent enzyme inducers are used, a higher maintenance dose of 12 mg/kg/day may be required. Rarely, in young children, very high doses of up to 20 mg/kg/day are required and well tolerated. ZNS is prescribed in 1 to 2 divided doses. Slow titration probably prevents some of the neurobehavioral adverse effects. If feasible, ZNS should be avoided in patients on acetazolamide, topiramate or ketogenic diet, because of increased risk of metabolic acidosis and nephrolithiasis. Adequate fluid intake is prudent in all patients on ZNS. Children are susceptible to hyperthermia due to decreased sweating and may require palliative measures.

ISSUES

Basic Science: Response and Resistance

Epileptogenesis has never been understood in terms of individual patient, thus, application of the understanding of AED mechanisms to customize drug therapy for every patient has not been possible. Of late, the importance of host factors in drug treatment of epilepsy is being realized. Patients who do not respond to AED may be inherently 'resistant' to them from the outset or may become 'refractory' to them because of multiple concurrent genetic or acquired factors. Recent research has focused on changes which prevent optimal drug-receptor interaction (target

hypothesis) and failure to attain sufficient levels inside the nervous system at the site of action (transporter hypothesis). Other emerging mechanisms for epileptogenesis include autoimmunity, inflammation, mitochondrial oxidative stress and electrical coupling in neurons or glial cells via gap junctions. These mechanisms represent potential targets for development of newer AED.

CLINICAL TRIALS

Most patients with new-onset epilepsy have a 50 percent likelihood of being controlled with their first AED at moderate dose. Additional 10 percent would attain seizure freedom with second monotherapy or add-on. Newer AED are, perhaps, unlikely to offer a huge advantage in terms of this 'efficacy'. However, it is expected that they offer substantial benefit in terms of 'effectiveness' which is a combined measure of efficacy and tolerability. However, most of the newer AED have not been evaluated as monotherapy in clinical trials. Since placebo-controlled design would be unethical, they are usually tested with alternative active-control designs like pseudo-placebo (lowest dose of standard treatment) or add-on-taper-to-monotherapy.

The duration of such trials is very short, e.g. presurgical withdrawal design. Further, failed superiority trials are taken to imply non-inferiority without any further analysis. Thus, the existing evidence for newer AED does not reflect clinical decision-making and there is need to design more representative studies, e.g. newer monotherapy versus conventional polytherapy. Overall, newer AED have not changed the prognosis for the whole epileptic population vastly; but have certainly improved outcome in selected patients. There are very few AED in phase III trials at present, and the wise thing as a clinician is to choose judiciously both the regimen and the patient to whom it is prescribed.

Febrile Seizures: Revisited

Amitava Sengupta

BACKGROUND

Febrile convulsions are the most common type of seizure disorder observed in the pediatric age group. They generally have a very good prognosis but may also indicate an acute critical infectious disease such as bacterial meningitis or sepsis.¹

Historically, febrile seizures were first described by the ancient Greeks. However, it was not until this century that febrile seizures were recognized as a distinct syndrome separate from epilepsy. In 1980, a consensus conference held by the National Institutes of Health (NIH) described a febrile seizure as, “An event in infancy or childhood usually occurring between three months and five years of age, associated with fever, but without evidence of intracranial infection or defined cause”.² It does not exclude children with prior neurological impairment and neither provides specific temperature criteria at which a seizure is considered febrile.

As per consensus of present day updates, febrile seizures are defined as seizures during fever, between six months and five years of age in the absence of intracranial infection.³

DEFINITIONS

Febrile seizures can be classified as simple, complex or atypical.

Simple febrile seizures are defined as seizures in neurologically healthy infants and children between six months and five years of age whose seizure is brief (<15 minutes), generalized, and occurs only once during a 24-hour period. This practice parameter excludes children whose seizures are attributable to a central nervous system infection (symptomatic febrile seizures) and those who have had a previous afebrile seizure or central nervous system abnormality (secondary febrile seizures).⁴

Complex febrile seizures are prolonged (last >15 minutes), have a focal onset and recur more than once in 24 hours. Complex febrile seizures may indicate a more serious disease process, such as meningitis, encephalitis, or cerebral abscess.⁵

Atypical febrile seizures vary from the above mentioned criteria, with features like unusual age of presentation or lower temperature than usual. The more the seizure differs from the classical syndrome; it is preferable to classify the event as “seizures with fever”. Febrile seizures should rarely be diagnosed in children who have afebrile seizures.⁶

Late onset febrile seizure, persistent febrile seizure, generalized epilepsy and febrile seizure (GEFS) and febrile status epilepticus (one seizure lasting 30 minutes or multiple seizures during 30 minutes) are special entities that need to be considered in the spectrum of febrile seizures.³

During the past two decades, the discussion on febrile seizures has moved from their natural history to their treatment. Now that we recognize that the majority of febrile seizures are benign, the aim of ideal management is to reassure parents. Knowledge of epidemiology, causes, and prognosis of febrile seizures will help us treat children and advise the parent’s rationally.⁷

EPIDEMIOLOGY

The prevalence rate of febrile seizures in young children is three to four percent.⁸ They are age dependent and are rare before nine months and after five years of age. The peak age of onset is 14 to 18 months of age.¹ Febrile seizures frequently recur, with recurrence rate of about 33 percent. Increased rates of recurrence ranging up to 50 percent are seen in first febrile seizures that occur below 12 months of age,⁸ seizures with low-grade fevers, when there is positive family history for febrile seizure and complex

features. Febrile seizures occur in all races and some studies demonstrate a slight male predominance. Remission is usually seen by the age of five years.³

Children with febrile seizures have a slightly higher incidence of epilepsy compared with the general population (2% versus 1%). Risk factors for epilepsy later in life include complex febrile seizure or neurologic abnormality prior to first febrile seizure, developmental delay and family history of epilepsy/febrile seizures.^{9,10} In patients with several risk factors, the incidence of epilepsy rises to nine percent as compared to one percent in children having febrile seizures with no risk factors.¹

PATHOPHYSIOLOGY

Febrile seizures occur in young children during a period in their development when the seizure threshold is low. This is a time when they respond with comparably higher temperatures. Animal studies suggest a possible role of endogenous pyrogens, such as interleukin 1 beta that, by increasing neuronal excitability, may link fever and seizure activity.¹¹ Preliminary studies in children appear to support the hypothesis that the cytokine network is activated and may have a role in the pathogenesis of febrile seizures, but the precise clinical and pathological significance of these observations is not yet clear.^{12,13}

The most commonly associated illnesses are upper respiratory infection, gastrointestinal infections, otitis media and roseola. Viral illnesses are the predominant cause of febrile seizures. In recent literature, the human herpes virus types six and seven have been implicated as possible specific causal agents. *Shigella* gastroenteritis also has been associated with febrile seizures. A direct toxicity affecting the central nervous system has been linked with this association.⁷ One study suggests a relationship between recurrent febrile seizures and influenza A.¹⁴

Febrile seizures tend to occur in families. In a child with febrile seizure, the risk of febrile seizure is 10 percent for the sibling and almost 50 percent for the sibling if a parent has history of febrile seizures as well.¹⁵

While polygenic inheritance is likely, a small number of families are identified with an autosomal dominant pattern of inheritance of febrile seizures, leading to the description of a “febrile seizure susceptibility trait”. Although the exact molecular mechanisms of febrile seizures are yet to be understood, underlying mutations have been found in genes encoding the sodium channel and the gamma amino-butyric acid A receptor.¹⁶⁻¹⁸ Studies have linked the febrile seizure gene to chromosomes 19p and 8q 13-21.¹

RISK FACTORS FOR DEVELOPING FEBRILE SEIZURES¹⁹⁻²²

- Family history of febrile seizures (first- or second-degree relative)

- History of developmental delay
- Preterm birth and low-birth weight
- Neonatal discharge at an age greater than 28 days (suggesting perinatal illness requiring hospitalization)
- Daycare attendance
- Maternal alcohol intake and smoking during pregnancy has a 2-fold increased risk.

Surprisingly there is no data to support the theory that a rapid rise in temperature is a cause of febrile seizures.

Presence of 2 of the above risk factors increases the probability of a first febrile seizure to about 30 percent.

RISK FACTORS FOR RECURRENT FEBRILE SEIZURES^{23,24}

About one-third of all children with a first febrile seizure experience recurrent seizures.

- Young age at time of first febrile seizure (less than 12 months of age)
- Relatively low-grade fever at time of first seizure
- Family history of a febrile seizure in a first-degree relative
- Brief duration between fever onset and initial seizure (less than one hour)
- Multiple initial febrile seizures during same episode (complex features).

EPILEPSY AND COGNITIVE OUTCOME

The greatest concern for the family following their child's febrile seizure is the risk of developing epilepsy (defined as two unprovoked seizures) in future. Children with febrile seizures have only a minimally greater risk of epilepsy in later life as compared to the general pediatric population. Risk factors for developing epilepsy in later life have been already enumerated in the section of epidemiology.

The effects of febrile seizures on developmental milestones and behavior appear to be limited. There is no evidence of brain damage, motor or intellectual compromise following simple febrile seizures.²⁵ Even febrile status epilepticus does not appear to affect long-term neuropsychological outcome. Literature does not reveal any difference between controls and children with febrile seizures on IQ testing and academic performance.⁷

Although usually benign, experiencing febrile seizures in their child is very frightening for all parents. Reassurance is the most important key-both by careful medical evaluation and proper counseling of the family.

HISTORY

The type of seizure (generalized or focal) and its duration should be described in order to help differentiate between simple and complex febrile seizures. Focus on the history of fever, duration of fever, and potential exposures to illness must be noted. A history of the cause of fever (e.g.

viral illnesses, gastroenteritis) should be elucidated. Some children may be suffering from a chronic seizure disorder and have aggravation of seizure episodes during fever. These are not febrile seizures and are termed as “seizures with fever.”

Recent antibiotic use is particularly important because partially treated meningitis must be kept in mind. A history of seizures, neurologic problems, developmental delay, or other potential causes of seizure (e.g. trauma, ingestion of any poisons) should be sought.

Physical

A clinician's initial prime approach should be to determine the cause of fever and to rule out meningitis, encephalitis or evidence of any other intracranial infection and pathology. A careful physical examination and evaluation often reveals otitis media, pharyngitis, or a viral exanthem. Serial monitoring of the patient's neurologic status is important. Focused clinical examination for meningeal signs as well as for signs of trauma or toxic ingestion is essential.

Differentials

A rationale list of possibilities should be entertained while working up a case of seizure associated with fever. These may include illnesses like: Meningitis and encephalitis, bacteremia and sepsis, epidural and subdural infections epidural hematoma and brain abscess.

Laboratory Studies

Variability exists in the approach to optimal management of patients with complex febrile seizures. Routine laboratory studies such as complete blood counts, cultures and routine chemistries including electrolytes are performed as part of a search for the source of fever and evaluation of the patient; in view of history and clinical findings. Patients with febrile seizures have an incidence of bacteremia similar to patients with fever alone.

Imaging Studies

Neuroimaging is not recommended in the evaluation of a neurologically healthy child with a first simple febrile seizure. They may be considered, if the seizures are complex or atypical, the child is neurologically abnormal, or if there are multiple febrile seizures.⁶

Electroencephalogram

The value of an electroencephalogram (EEG) in the evaluation of febrile seizure has not been promising. It shows deviation from normalcy in the early phase in one-third of affected children. Both focal and generalized abnormalities have been described in the immediate postictal period. However, these abnormalities do not predict the risk of a recurrence or risk of epilepsy in the future.⁷

An EEG is not necessary in the routine evaluation of a child with a first febrile seizure. It may be considered in the work-up of children with complex or atypical seizures or with additional risk factors for epilepsy in future.¹

EEG is useful in ruling out possibility of encephalitis in a child with complex febrile seizures or prolonged postictal period.⁷

Lumbar Puncture

Lumbar puncture is usually not recommended for children with first simple febrile seizure.²⁶ Meningitis can present with a seizure. However, the seizure usually is not the only sign of meningitis. Patients who have a first-time febrile seizure and have an unusually prolonged postictal period should be evaluated for meningitis. Reviews of the medical literature report less than 5 percent incidence of meningitis in children presenting with seizures and fever.

Risk factors for meningitis in patients presenting with seizure and fever include the following:

- Visit to a healthcare facility, 48 hours prior to the seizure episode
- Seizure activity at the time of arrival in the emergency
- Focal seizures with suspicious clinical features relating to meningitis
- Prolonged postictal period 1996, American Academy of Pediatrics (AAP) recommendations for lumbar puncture
- Strongly considered in infants younger than 12 months presenting with fever and seizure
- A lumbar puncture is considered in patients aged 12 to 18 months, if seizures are complex with prolonged postictal phase
- Lumbar puncture should not routinely be done in children older than 18 months, unless there is history or clinical features suggestive of intracranial infection.

Clinicians must be sensitive to the fact that often, recognizing meningitis in infants and young children may be difficult and the range of experience in the evaluation of pediatric patients among attending physicians is crucial. We should never assume that a child with a previous febrile seizure will not develop meningitis. Children with persistent fever should be closely monitored, even if the initial CSF examination is normal.

MANAGEMENT

This primarily includes rationale approach towards investigations with restraint, treatment of the acute episode and prophylaxis for future episodes with adequate and proper family counseling.³

Antipyretics do not prevent recurrences, however, controlling the fever with antipyretics does give comfort to the child and reassurance to the family.¹ Acetaminophen (15 mg/kg/dose), ibuprofen (5-10 mg/kg/dose) or mefenamic acid (3-5 mg/kg/dose) are preferred medications.

Acute Management

Termination of active seizures lasting two to five minutes.

Benzodiazepines are rapidly absorbed and have a short, effective half-life. Hence, they are used as first line drugs of choice for aborting acute seizures. However, the clinician must be aware of side effects, such as somnolence, lethargy, irritability, ataxia and deal with them accordingly. The two drugs most widely used in this group are midazolam and diazepam.

Home Therapy

Rectal diazepam has been well documented in literature for treatment of acute seizures.²⁷

Studies comparing efficacy of intranasal midazolam to diazepam for acute treatment of prolonged acute febrile seizures, found both drugs to be equally effective.²⁸

Further, some studies from the year 2000 onwards have reported that intranasal midazolam was effective in ending acute seizures within ten minutes.²⁹⁻³¹ Intranasal midazolam is a reasonably safe and preferred route for terminating acute seizures in childhood. It has a rapid onset of action, no significant effects on respiration, is easy to administer and is more socially acceptable.³²

Dosages

- Midazolam – buccal/nasal spray (0.2-0.4 mg/kg/dose). During nasal instillation, the dosage is to be divided equally into each nostril. Intranasal midazolam is available in an atomizer which contains 50 metered doses of 0.5 mg/ metered dose. Intranasal midazolam solution contains 5 mg/ml. The preparation is available with the brand name of “INSED”.
- Rectal diazepam (0.5 mg/kg/dose), buccal (0.4-0.5 mg/kg/dose), intranasal (0.2 mg/kg/dose). Rectal diazepam is available in the form of gel, and also the injectable preparation of the drug can be given rectally.

Hospital Therapy

Active seizures should be treated with airway management, high-flow oxygen, supportive care and anticonvulsants as necessary.

- Midazolam (0.1-0.2 mg/kg/dose intravenous bolus)
- Diazepam (0.2-0.5 mg/kg/dose intravenous bolus).

Infusions may be used when indicated in situations such as status epilepticus.

Intermittent Prophylaxis

In majority of children who experience febrile seizures in early life and their good outcomes make it unfeasible to justify long-term administration of anticonvulsants.²⁸ However, intermittent prophylaxis, administered when children at risk for febrile seizures have fever is prudent.

The ideal approach to prevent recurrence of febrile seizures is to intervene at the onset of febrile illness by initiating the recommended anticonvulsant.

Intermittent diazepam therapy for the prevention of recurrence of febrile seizures has been well documented in literature and shown to be effective.³³

Intermittent clobazam therapy is also as effective in the prevention of recurrence of febrile seizures. Clobazam induced ataxia is much lower than that reported with diazepam.³⁴ As per present day recommendations, oral clobazam is the preferred drug in intermittent prophylaxis for preventing recurrence.³

Dosages

- Clobazam
The therapeutic dosage of clobazam ranges from 0.3 to 1 mg/kg/day.
Recommendation for Intermittent Prophylaxis:
 - (0.75 mg/kg/24 hours) in 2 divided doses, for two to three days.³
 - Doses as per weight category³⁴
 - Up to 5 kg – 5 mg/day
 - 6 to 10 kg – 5 mg/twice daily
 - 11 to 15 kg – 7.5 mg/twice daily
 - >15 kg 10 mg/twice daily
 Duration two to three days.
- Diazepam
Oral diazepam at the onset of each febrile illness-0.3 mg/kg/dose every eight hours (1 mg/kg/24 hours) for two to three days duration.¹

Prolonged Prophylaxis

Continuous anticonvulsant prophylaxis for preventing recurrent febrile seizures is no longer recommended for most children. Phenobarbitone usage decreases recurrence of febrile seizures but also results in compromise of cognitive function in treated children as compared with untreated children.¹

Special Circumstances for Consideration of Continuous Prophylaxis³

- Febrile seizure recurrence more than six per year, in spite of regular intermittent prophylaxis
- Severe cases of febrile status epilepticus

Age group less than one year- phenobarbitone as per recommended doses: for a period of one to two years

Older children- sodium valproate as per recommended doses: for a period of one to two years

In this regards, a discussion with the parents about the harms and benefits of prolonged anticonvulsant therapy should have a holistic approach along with proper counseling.

INPATIENT CARE

The decision to admit should be individualized. Most patients should be observed in the emergency room (ER) until awake and alert.

Conditions requiring admission of the patient include the following:

- More than one seizure within 24 hours
- Unstable clinical status
- Lethargy beyond the postictal period
- Uncertain home situation
- Unclear follow-up care.

FOLLOW-UP ADVICE

Medical re-evaluation of discharged patients and parental education should be arranged in a follow-up appointment within 24 to 48 hours. Discharge medications include antipyretics and antibiotics, if indicated (e.g. otitis media, pneumonia).

PATIENT EDUCATION

Parents should be taught what to do if their child has another seizure. They should be counseled on the benign nature of febrile seizures and educated about the role of Intermittent prophylaxis therapy. Also, parents should be reassured that simple febrile seizures do not lead to neurologic problems or developmental delay.

SPECIAL CAUTIONS

- 2008 Clinical Practice Guideline for the Long-term Management of the Child with Simple Febrile Seizures:
 - Evidence shows preponderance of harm over benefit with continuous or intermittent use of anticonvulsants for children with one or more simple febrile seizures.³⁵
 - The AAP guideline released in 2008 does not recommend prophylactic use of diazepam as the risk outweighs the benefits.³⁵
- Studies report that diazepam, given orally or rectally every eight hours during febrile illnesses, is effective in preventing recurrence of febrile seizures.^{36,37} However, these benzodiazepines can cause lethargy, drowsiness, and ataxia, and sedation, which could mask an evolving central nervous system infection.
- A strong association exists between febrile status epilepticus or febrile seizures characterized by focal symptoms and later development of temporal lobe epilepsy.^{38,39}

PREVENTION

Influenza A is now having a more established role in the etiology of febrile seizure, both acute and recurrent.

Vaccination against influenza A in the flu season may have a role in preventing development of both acute and recurrent febrile seizures.⁴⁰

CONCLUSION

Febrile seizures are a frequent and benign disorder of infancy and early childhood. In a majority of children, they represent the expression of a genetically inherited response to fever. For these children, usually no treatment is required and parents and family should be reassured and adequately counseled. It is rare that febrile seizures represent early evidence for later epilepsy. Electroencephalography is not predictive of epilepsy in the future in children with febrile seizures.

Intractable Epilepsy in Children and Adolescents

Nandan Yardi

INTRODUCTION AND EPIDEMIOLOGY

Epilepsy is one of the important public health problems in developing¹ and developed countries accounting for a prevalence (active cases, with at least one seizure in the last 5 years) of 0.5 to 1 percent of the general population while incidence (occurrence of new cases, usually in 1 year) is higher in developing countries at 70-100/100,000 population per year. A treatment gap of 85 to 90 percent, defined as the percentage of persons with active epilepsy, who at any given time, are not receiving treatment, has been found in most developing countries including India in urban, rural and tribal populations.^{2,3}

Five community-based surveys from India have revealed prevalence rates per thousand population of 2.5 for Kashmir,⁴ 3.6 for Parsis of Mumbai,⁵ 4.5 for tribals of western Maharashtra,³ 4.4. for Karnataka⁶ and 4.9 for Kerala.⁷ Age specific prevalence of epilepsy was higher in the first three decades of life.

Although believed to be intractable and progressive in the past two centuries by many authors, it has become evident in the present century with advances in various treatment options, that a few unfortunate individuals have intractable epilepsy. The challenges for this century are reduction of the treatment gap and management of intractable cases. When misdiagnoses, misclassification, occasional seizures, pseudoepileptic seizures and noncompliance are excluded, the true intractability of epilepsy is less than 20 to 30 percent and not more than 5 to 10 percent of patients on optimal and appropriate antiepileptic therapy will prove to be truly intractable, when these factors and surgery are ruled out.¹⁴ The most common misdiagnoses are vascular collapse and arrhythmias, psychiatric causes, breath holding spells day dreaming and other sleep disorders (parasomnias, night terrors) and migraine or vertigo that need to be carefully ruled out at the outset by a careful history and documentation by video-EEG.

DEFINITION OF INTRACTABILITY

The concept of intractability has to take into account not only the seizure frequency, but also severity based on severity rating systems, circadian variations, and most importantly the impact of the disorder on the persons well-being and level of scholastic and social functioning and is usually graded according to how aggressively previous treatment has been pursued. Several population based studies have shown that 70 to 80 percent of persons with newly diagnosed epilepsy have a 1 year remission⁸ that most remissions occur early.⁹ Still we are left with 20 to 30 percent of patients with difficult to treat seizures and are intractable.

There is a cluster of intractable seizures in infancy and early childhood. In infancy the immature brain is especially susceptible to seizures due to, among other things, enhanced excitation, diminished inhibition and underdeveloped nigral seizure control.¹⁰ These and other susceptibility factors predispose to many intractable syndromes, peculiar to infancy and early childhood, such as early infantile epileptic encephalopathy (Ohtahara's syndrome), West syndrome, Lennox-Gastaut syndrome, epilepsia partialis continua (Kojewnikow syndrome and Rasmussen's encephalitis) and the Dravet syndrome. In adolescence, partial seizures, progressive myoclonic epilepsies and lesion epilepsies tend to be associated with intractability.

Predictors of Intractability

The predictors of intractability for seizures in children were symptomatic etiology of seizures, occurrence of status epilepticus, high initial seizures frequency and poor short-term outcome of therapy.¹¹ Early onset of epilepsy in infancy, abnormal neurological status, neurotic or psychotic comorbidity, a grossly abnormal EEG, presence of

multiple seizure types are other predictors. Individual seizure types such as tonic, atonic or myoclonic have a different outcome on long-term follow-up. There is a marked overlap between individual risk factors necessitating a multivariate analysis.

Two classical population based studies^{12,13} have suggested that most patients that achieve seizure control do so in the first-two years of the onset of epilepsy. This knowledge has been utilized to make the working definition of intractable epilepsy—patients who continue to have two or more disabling seizures per month for a period of two years or more in spite of adequately monitored and supervised antiepileptic drugs, appropriate for the seizure type and syndrome, using two monotherapies (some include one polytherapy) are said to be intractable and need evaluation in a comprehensive epilepsy care program from an epileptologist and his team. Depending on individual situations and substrates (in this post-MRI era), this period is sometimes shortened before presurgical evaluation is conducted, as some conditions like mesial temporal sclerosis or certain hamartomas that are highly epileptogenic such as a dysembryoplastic neuroectodermal tumor, cause disruption of the quality of life and learning, needing early surgical attention.

Conditions Likely to be Associated with Intractability

In childhood and adolescence, the following conditions are likely to be resistant to therapy and have a peculiar natural course with and without antiepileptic medication.

These are progressive myoclonic epilepsies and other progressive metabolic encephalopathies.

- The triad of age dependent epileptic encephalopathies—West syndrome, Ohtahara's syndrome, Lennox-Gastaut syndrome.
- Rasmussen encephalitis and infantile hemiplegia.
- Neurocutaneous syndromes like tuberous sclerosis and Sturge-Weber syndrome.
- Cerebral malformations and disorders of neuronal migration.
- Granulomas—Neurocysticercal and tubercular.
- Cerebral palsy and hypoxic ischemic encephalopathy.
- Localization related epilepsies, both symptomatic and cryptogenic.
- Hippocampal or mesial temporal sclerosis, sometimes seen in childhood but the commonest structural cause in adolescence and early adulthood.
- Vascular malformations including cavernomas and AVMs.
- Indolent tumors like gliomas, meningiomas, dysembryoplastic neuroectodermal tumors (DNETs).
- Scars—postmeningitic, vascular damage, hypoxic ischemic damage associated with difficult childbirth or otherwise, hypoglycemic damage, traumatic damage.

Investigation of Intractable Epilepsy

The objectives of investigation are to confirm that the person has epilepsy and to rule out nonepileptic conditions masquerading as episodic seizure like events, to clarify the nature of the seizure type and to make a syndromic diagnosis if possible, so as to treat generalized epilepsies and idiopathic partial epilepsies with appropriate antiepileptic medication. At this point, it is an opportunity to re-evaluate the past antiepileptic drugs used and ensure that therapeutic use has been documented to determine pharmacoresistance to various drugs used,¹⁷ preferably taking into account the past drug levels findings, if available. It is important to localize focal nonidiopathic epilepsies, to confirm lateralization of the seizure focus, and to determine the operability of the focal lesion. This determines ideal selection of surgical candidates with concordance for seizure semiology, imaging, and electrographic and neuropsychological tests. It ensures that the surgery will not result in untoward disabling neuropsychological deficits.

All these are part of the presurgical evaluation indicated in all patients with difficult to treat seizures.

Protocol for Presurgical Evaluation

A protocol for presurgical evaluation may need to be extensive depending on what epilepsy syndrome we are dealing with and as it becomes apparent whether it is a defined temporal lobe syndrome, the evaluation may be discontinued so as to have a low cost of presurgical evaluation.^{15,16} In extratemporal lesions, especially localized to eloquent areas, usually the evaluation needs to be more extensive, so as to evaluate the safe operability of the lesion.

The protocol we follow at the yardi epilepsy clinic, Pune and comprehensive epilepsy center at Jehangir Hospital, Pune consists of:

Detailed medical history—evaluate the past treatments, drug levels, seizure type, frequency, EEGs, medical and neurological examinations.

Sixteen channel wake and sleep scalp EEG with activating procedures—hyperventilation and photic stimulation.

MRI scans—epilepsy profile 1.5 T or 3 T MRI study for hippocampal volume and sclerosis. Use of coils brings out cortical malformations better and can be effectively used with 1.5 T MRI and review of previous CT and screening MRI studies:

- Neuropsychological evaluation
- Psychosocial evaluation
- Psychiatric evaluation
- Visual field testing
- Ictal video scalp EEG recording to characterize the seizures, and lateralize the seizures and to rule out psychogenic seizures (3-5 days or till adequate habitual seizures are recorded)

- Intracarotid amobarbital (Wada) test for evaluation of language and memory lateralization may be done but depends on availability of the medication. Alternatively, if MRI scan may help to localize the eloquent areas such as speech and memory using special protocols for evaluation
- Single photon emission spectrophotometry (SPECT) scan, SISCOM and positron emission tomography (PET) using radiolabelled ligands to define various areas of brain by imaging techniques have been useful in recent times
- Magnetoencephalography (MEG) and use of intracranial or depth electrodes need to be used judiciously to define the epileptogenic cortex.

All findings are discussed in a multidisciplinary case conference by concerned specialists to decide the feasibility and planning of the surgical procedure planned and the expected outcome.

HISTORY

Obtaining a detailed history from the patient and relatives who have been onlookers, for the habitual seizures, is very important to determine auras, and automatisms, (oroalimentary or gestural), events like ictal paretic posturing of the upper limb, ictal dysphasia, spitting, and postictal Todd's palsy that help in localization. A detailed neuropsychiatric and psychological evaluation may help to rule out nonepileptic pseudoseizures in most patients especially when both true and nonepileptic-seizures exist in the same patient.

Clinical Examination

Often unrewarding in patients with focal epilepsies, it may yield useful information at times in the form of mild hemiparesis, visual fields defects, and mimic facial palsy, to help lateralize the focus.

Scalp EEG

Awake and sleep-deprived sleep studies have a higher positive yield than a wake record which depends on the strict protocol followed in recording and interpretation of EEGs that is critical to tailor the further evaluations in the protocol. The most reliable EEG findings in intractable patients are interictal spike or spike wave discharges from one temporal lobe and temporal intermittent rhythmic delta activity (TIRDA) but bitemporal spikes or spike wave activity is commonly seen in one-third of patients. Tandem sleep and wake records are important to rule out ESES (electrical status epilepticus in slow wave sleep).

Benign epileptiform variants such as wicket waves, 14 Hz spikes, and mu rhythm have to be carefully ruled out.

Prolonged Video EEG using Scalp Electrodes by Digitized Monitoring

A continuous digitized video EEG monitoring of habitual seizures is required for localization of electro-graphic abnormality and to correlate for semiologic concordance. Often when the seizure frequency is not very high, step-wise reduction of AEDs is done in admitted patients to allow seizures to be recorded. A handycam imaging for studying semiology and time locking with digital EEG is an adequate improvised tool for low cost presurgical evaluation, in straight forward temporal lobe cases showing unilateral hippocampal sclerosis and volume loss, when correlated with a good MRI study, in start up centers in developing countries.¹⁵ At this point of time, one can confidently rule out pseudoseizures and nonepileptic events.

In persons with unilateral temporal interictal abnormalities, it is mandatory to record at least 2 to 3 habitual seizures with concordant electrographic onset but with bitemporal interictal abnormalities, at least 5 to 7 seizures need to be recorded to make the decision about lateralization of the electrographic abnormality to determine the side of resection.

Semiological correlation is looked for in the analysis of these seizures. Features such as early head turning, unilateral limb automatisms, unilateral blinking and ictal nose wiping automatisms indicate ipsilateral localization while dystonic limb posturing, late head turning localize to the opposite hemisphere. Speech arrest and prolonged postictal dysphasia localize to dominant hemisphere while ictal spitting, ictal vomiting and ictal speech localize to nondominant hemisphere.

Neuroimaging: CT scan is not the modality of choice in epilepsy except when one looks for calcification in lesions such as DNET, neurocysticercosis or tumors or there is a discrete abnormality in a CT scan. A screening MRI scan is usually done in persons with epilepsy and may provide information about focal lesions but may not contain critical information about cortical dysplasia and hippocampal sclerosis or volume loss unless specific sequences are ordered as in an epilepsy profile MRI study. Angled coronal FLAIR sequences and spoiled gradient imaging are a must in each epilepsy profile study with Hippocampal volumes following thin sections to determine subtle abnormalities. Problems arise when there are bilateral Hippocampal abnormalities and dual lesions consisting of neocortical lesions with secondary hippocampal lesions.

MRI imaging and V EEG have revolutionized epilepsy presurgical evaluation and are the mainstays of evaluation, in experienced hands to give a cost effective yield and need to be ordered with great care at centers with good machines and experienced neuroradiologists to avoid repetitive costs from poorly ordered MRI studies.³¹

Neuropsychological assessment: Neuropsychological tests are the mainstay to determine the cognitive abilities of the brain and psychological state of the person with resistant epilepsy. It tells us about the dominance of the hemispheres, the various functions of various lobes from lobe function tests and chances of postresection memory loss. It is important to evaluate the quality of life issues pre and postresection.

Therapeutic drug monitoring: Plasma drug monitoring is important because of the large interindividual variation in blood levels of various antiepileptic drugs¹⁷ and interaction especially as resistant seizures are associated with polytherapy. The monitoring of drug levels has to be used and interpreted with great care to get maximum benefit for optimum seizure control.

Functional mapping: Noninvasive functional procedures such as SPECT, PET, functional MRI scans (fMRI), MR spectroscopy (MRS) and magnetoencephalography (MEG) with dipole localization, are some of the tests that may have to be used for difficult cases, especially extratemporal, neocortical epilepsies, to provide additional information regarding functional areas like memory, speech, language to avoid unacceptable neurological deficit following resection and to determine the appropriate type of resective procedure.^{18,19}

Invasive monitoring: Whenever the results of noninvasive monitoring (scalp EEG, video EEG and MRI and neuropsychological tests) are conflicting one may have to resort to invasive monitoring to get additional information. Mesiotemporal onset seizures may be missed on these tests or are poorly localized and need sphenoidal electrode placement below the foramen ovale to detect the ictal and interictal spike discharges.^{20,21} For extratemporal neocortical lesions, grids or strips or epidural pegs or intracerebral depth needle electrodes are used singly or in combination to obtain maximum information about interictal and ictal events and for functional mapping. These are associated with higher morbidity than the noninvasive monitoring and the results of resection of extratemporal lesions are not as good as temporal resections²²⁻²⁴ and noneloquent areas may be resected with limited presurgical investigation, if cases are chosen carefully, with fairly good results, especially if guided by intraoperative corticography.¹⁵

Intracarotid Amytal Test (Wada's Test)

The Wada's test is used in children above the age of 12 years and adults to determine the lateralization of language to one of the other hemisphere. The injection of amobarbital dose in one carotid is made to anesthetize each hemisphere in turn and language and memory are assessed for the nonanesthetized hemisphere using a standardized protocol for carefully assessing and interpreting the findings.²⁵ Amobarbital is not easily available in India.

Clinical Approach to Intractable Epilepsy

The first step in evaluation of intractable epilepsy is to determine if the seizures exist and therefore to rule out nonepileptic events. Then one determines the seizure type and treats generalized seizures and idiopathic focal seizures using appropriate antiepileptic drugs in therapeutic range guided by antiepileptic drugs where possible. Newer antiepileptic medications may be tried in polytherapy taking great care to avoid interactions. Alternative therapies may be tried. Polytherapy may be tried in a rational manner using drug combinations with different mechanisms of action based on the recent developments in receptor understanding. Many times, monotherapies is better than polytherapy in achieving an acceptable level of seizures with minimal side effects that may sometimes occur with polytherapy and may be more disabling than the seizure themselves.

However, nonidiopathic focal (lesional) epilepsies need to be picked up early and subjected to appropriate presurgical evaluation to determine respectability of the electrographic focus. Appropriate counseling of the patient and parents/relatives needs to be done from time to time as the presurgical evaluation progresses. Questions related to quality of life issues such as schooling, employment, driving, marriage, parenting and costs of medical and surgical therapy need to be discussed. Often, the direct and indirect costs of medical therapy are more in the long-term, especially if expensive new antiepileptic medications are used, as against resectable lesions where surgery may offer cure and an improved quality of life.

EPILEPSY SURGERY

Surgical treatment should be considered and performed before the negative consequences of the epilepsy have become destructive and irreversible, and before spread of the epileptogenicity has made the person inoperable. Yet surgical therapy should not be considered unless there is a reasonably good chance of improving the patient's quality of life (QOL). Establishment of the general and specific criteria for surgery is a process, which takes some time. For proper timing, it is preferable that a multiprofessional team headed by the epileptologist evaluates the patient at regular intervals, at a comprehensive epilepsy care center—it should not be considered as the last resort after AED's in all combinations have been tried for adequate periods—a process that may, mathematically, take up most of the patients and physicians lifetime.

CANDIDATE FOR EPILEPSY SURGERY

- Persistent intractable seizures inspite of maximally tolerated AEDs—the period of observation depends on the seizure type, frequency, type of epilepsy and etiology-usually 2 years

- Evidence of medical, social and educational disability due to seizures. Poor QOL which is likely to improve after surgery.
- Diagnostic evidence points to a common and single epileptogenic focus by EEG, imaging, neuropsychology and seizure semiology.
Discordant results are associated with poor surgical outcome.
- Intracarotid amytal test (Wada's test) shows that the contralateral temporal lobe can sustain memory and speech independently, usually after 10 years of age.

Surgical Procedures for Epilepsy

The various surgical procedures for intractable epilepsy carried out are:

- Resective procedures
- Removal of a mass of epileptogenic tissue:

Standard anterior temporal lobectomy in cases of intractable partial epilepsy with onset in temporal lobe and normal memory function in contralateral temporal lobe.

Selective Amygdalohippocampectomy—intractable partial epilepsy with seizure onset in medial temporal lobe with contralateral borderline memory function.

Removal of an epileptic focus or discrete lesion—lesionectomy where there is gross removal of malfunctioning brain tissue.

Focal Corticectomy

Functional Procedures

Disconnection procedures—corpus callosotomy—when there is unilateral cerebral.

Pathology causing focal plus secondary generalized seizures and especially with frequent atonic seizures in mentally retarded children.

Separation of epileptogenic cortex from the rest of the brain—multiple subpial transactions: When there are intractable partial seizures originating in unresectable foci in primary cortices especially eloquent areas serving the functions of motor, speech, language and memory.

Hemispherectomy: When there is evidence of major lesions involving one hemisphere and there is no useful opposite hand, being involved in a hemiparesis.

Anterior Temporal Lobectomy and

Amygdalohippocampectomy: En Bloc Resection

The most common surgical procedure for epilepsy is the anterior temporal lobectomy with en bloc removal of amygdala and hippocampus (ATL). It is performed by standard temporal craniotomy under propofol or pentobarbital anesthesia and consists of resection of 5 to 6 cm block of temporal neocortex along with the superior temporal gyrus, and anterior two-thirds of the hippocampus

lateral two-thirds of the Amygdala along with the uncus and the parahippocampal gyrus.

With proper selection of concordant cases having MTS, nearly 60 to 70 percent may become seizure free after ATL, while 80 to 85 percent cases may have substantial reduction in seizure frequency. Most patients have a significantly improved quality of life and some may improve their verbal and performance IQ by up to 10 percentage points. Indicators of good long-term seizures free outcomes are—a lesion detected in mesial temporal lobe, unilateral temporal interictal EEG spike focus, presence of abnormal pathology in the resected surgical specimen and absence of disabling seizures in the first year of resection.^{26,27} Absence of pathology in the resected specimen is a negative prognostic factor.

Extratemporal Resection

Surgery of extratemporal epilepsy is both difficult and has a poor outcome than that for temporal lobe epilepsy. The reasons being that it is difficult to define the epileptogenic zone with certainty and to do so requires much noninvasive and invasive investigation that is both cumbersome and expensive, there is rapid spread of the seizures discharge to contiguous regions and along long association fibers to distant regions causing varied and confusing manifestations and difficult electrographic localization, possibly more diffuse epileptogenesis and dual pathology, more frequent overlap with adjacent eloquent areas limiting resectability. The outcomes do not differ much from frontal to parietal to occipital lobe and range from 45 to 55 percent of seizure reduction and lower figures for seizure freedom and better outcomes have been associated with MRI detectable lesions than just electrographic localization without discrete MRI lesion, and when there is a single epileptogenic lesion.^{28,29}

Corpus Callosotomy

It is the surgery of choice in mentally retarded children or adolescents with frequent drop attacks as seen in Lennox-Gastaut syndrome and multifocal epilepsy from both hemispheres with frequent generalized seizures. It has an outcome for reducing disabling drop attacks of nearly 80 percent and greatly improves the QOL in this subgroup of patients. Usually the anterior two-thirds of the corpus callosum are adequately resected to avoid a disconnection syndrome.

Hemispherectomy

The classical hemispherectomy, with complete disconnection of one hemisphere from the rest of the brain, was recommended for the children who have multiple or large epileptogenic areas localized to one hemisphere and there is no useful hand control of the opposite side, being

involved in a hemiparesis. Recently variations of the procedure have been more commonly used in various centers, to avoid late complications arising from superficial cerebral hemosiderosis. These are modified hemispherectomy, functional hemispherectomy, shunted hemispherectomy and hemidecortication. It improves the QOL in children with Rasmussen's encephalitis, HHE syndrome. Sturge-Weber syndrome and hemimegalencephaly, also reducing the spread of seizures, although the patient may still get partial seizures.

Multiple Subpial Transactions (MST)

Lesions located in the vicinity of eloquent areas such as motor and speech areas, it is mandatory to minimize the excised volume without compromising seizure control due to the fact that epileptic discharges propagate tangentially throughout the cortex while impulses controlling voluntary movements propagate in a radial direction, a series of vertical cuts can be made to control the epilepsy and yet preserve normal function using special instruments (Morrell's procedure). It is a safe option to reduce seizures without causing neurological deficits.

Stereotactic Procedures

Stereotactic lesionectomy, radiofrequency lesionectomy, volumetric resections and radiosurgery have variable safety and are not universally accepted but are effective in controlling intractable seizures with an advantage of resecting deep tissues involving functional and eloquent cortex, having a relatively low morbidity.

Complications of Epilepsy Surgery

Advanced techniques of presurgical evaluation, using the electrophysiology and imaging modalities and intraoperative evaluations and a microneurosurgical techniques sometimes with the stereotactic frame, has reduced the rate of complications following resective epilepsy surgery and permanent neurological morbidity of below 2.5 percent transient neurological morbidity of 3 percent, totaling about 5.5 percent, in most reputed centers. Mortality is nil to about 1 percent.

The complications expected are discussed with the relatives and patient preoperatively and are related to the type of procedure being done. Homonymous superior quadrantic hemianopia (due to optic tract or optic radiation being involved), language deficits such as nominal aphasia or dysphasia, manipulation contralateral hemiparesis caused by handling and spasm of sylvian artery, anterior choroidal artery supplying the cerebral peduncle, or perforating arteries supplying internal capsule causing lacunar infarcts may occur. Mostly, a reversible hemiplegia occurs due to temporary spasm but cases of permanent hemiplegia have also been reported.

Personality changes are seen with frontal lobe resections, Gerstmann syndrome seen with inferior parietal lobule resections and syndrome of mutism, disconnection syndrome of apraxia of nondominant lower limb contralaterally, with incontinence is seen with corpus callosum resections.

Classical hemispherectomy may lead to a delayed cerebral hemosiderosis. That may be prevented by the modified procedures or hemispherotomy.

Newer AEDs

Although the number of newer antiepileptic medications available for clinical use is growing in number, it is accepted that they have a limited impact on true intractable epilepsy because of their limited efficacy and frequent side effects. Less than 7 to 10 percent persons become seizures free and for this subgroup of intractable epilepsy it is not sufficient for improving the quality of life if they have a significant reduction of seizures. The newer antiepileptic drugs have modes of action which may be on sodium channels, calcium channels, potassium channels, GABA, GABA transaminase, NMDA³³ or novel receptors like SV2A, on neuronal membranes and synaptic regions, with sometimes better tolerability and efficacy as compared to standard AEDs, enabling one to choose the drug as add on or monotherapy, to get better effect. Special subgroups of patients with epilepsy may benefit from these appropriately chosen drugs, e.g. children with West or Lennox Gastaut syndrome, women of childbearing age with epilepsy and obese or underweight children.

Most drugs are effective for partial epilepsy and some for generalized epilepsy as well. Detailed discussion is better sought elsewhere being outside the scope of this chapter.^{34,35}

Unconventional Therapies

Psychological approaches to treatment of seizures include direct and indirect inhibition of cortical areas responsible for seizure generation and contingent relaxation techniques. Seizure precipitants are looked for specifically and avoided and desensitization procedures are useful. Acceptance and commitment therapy and other short course psychotherapies, negative slow cortical potentials, and parasympathetic stimulation of the limbic system are of use in few patients. Parasympathetic stimulation may be effected by vagus nerve stimulation or yoga and have shown to be of benefit in some patients.^{30,32} Left vagus nerve stimulation through an implanted, programmable stimulator device has been used for over 7 years especially in persons who cannot undergo surgery due to multiple foci, generalized epilepsy or other causes and has shown that 44.1 percent patients achieved more than 50 percent reduction of seizures at 3 years but only a few are seizure free.

Movement Disorders in Children

Nandan Yardi

INTRODUCTION

Although Parkinson, Huntington, Sydenham and others have recognized the disorders of movement, including those affecting children for centuries, in the classical descriptions of the disease, the interest in movement disorders in children has been only recent. These conditions are usually transient lasting for days, weeks or months, unlike the neurologic conditions in adults that may last a lifetime. The conditions of movement disorders in children are often self-limiting, resolving completely, often without neurologic sequel. In otherwise normal infants, choreiform, choreoathetoid and dystonic movements may be apparent for several days or weeks with subsequent resolution and normal development. Examples are paroxysmal torticollis in infancy,¹ benign myoclonus of infancy (that must be differentiated from Infantile spasms) and Precht's choreiform movements² seen in the extended hands of some children, all of which resolve without neurocognitive or motor sequel. Stuttering, motor tics and vocal tics are very common in children and are not necessarily early manifestations of the Gille de la Tourette syndrome.

The childhood movement disorders are difficult to classify based on the type of movement because observation has been the mainstay of diagnosis. The problem is that many of the disorders have several manifestations such as bradykinesia with rigidity and tremor (Parkinson's disease); tremor, dystonia and rigidity (Wilson's disease); and dystonia, spasticity and bradykinesia (Juvenile dystonia-Parkinsonism). At any given time of clinical examination, one manifestation may be prominent and misleading to the clinician. Evaluation of movements using videotaping at the clinic or home has been of great help in evaluation by experts in movement disorders.

Topographical classification has been used consistently for Parkinsonism, chorea and tremor. However, focal, hemifocal, multifocal, segmental and generalized forms

that have been described for dystonia are not useful as dystonia often progresses from focal forms to segmental, hemi- and generalized forms over months or years. It is important to exclude focal lesions of the basal ganglia by magnetic resonance imaging scan with contrast enhancement, whenever these major clinical manifestations are presented focally.³

Out of respect to the conventional traditions of neurology, most clinicians classify movement disorders as those conditions with predominantly hypokinesias (Parkinsonian state) and those with hyperkinesias (choreas, tremors, dystonias, ballismus, choreoathetosis, and tics). Although this framework is useful, kinetic manifestations often overlap in a particular syndrome. The bedside manner of classification is to include the neurological basis for the presenting manifestations such as genetic, developmental, metabolic, traumatic, degenerative, infectious, oncology, intoxication and so on.

Neuropathologically, the pathologic process is imposed on an evolving and developing neural substrate, partially explaining the prominent rigidity and bradykinesia in Juvenile Huntington's chorea and the dystonia in levodopa-responsive juvenile idiopathic dystonia – Parkinsonism syndrome. Fluctuations may occur in the clinical manifestations such as temporary deterioration of dystonia or chorea due to intercurrent infections and a latent period before onset of dystonia in a child with hemiplegic cerebral palsy. Disorders of movement have been traditionally ascribed to the abnormalities of the central nervous system and of basal ganglia and the connecting structures in particular, with a strong evidence of structural and ultrastructural basal ganglia abnormalities in Parkinsonism, Huntington's chorea and many focal dyskinesias. Many other conditions presenting with movement abnormalities have no obvious neuropathological basis for the clinical manifestations and are often

considered biochemical in nature based on the response to a specific pharmacological treatment. The neurochemical basis of classification of movement disorders has been studied for decades particularly for Parkinson's disease (dopamine deficiency) and Huntington's chorea (gamma amino butyric acid deficiency). There is postulation and some evidence of multiple neurotransmitter and neuro-modulator deficits, making this classification nonviable, as single agent replacement therapy is usually only effective in relieving the specific abnormal movement and not associated movements or progressive neural degeneration. Recent studies are aimed at neuronal interactions and neural growth factors that are involved in nervous system development and functional maintenance. There is a defect in complex- I of the Oxidative phosphorylation pathway in brain, muscle and platelets of patients with Parkinsonism.⁴

A genetic basis for many movement disorders has been recognized for a few centuries. Many dominant conditions have variable clinical expression and improper penetrance, and such multiplex families or trios require investigation using molecular or specific markers. Mitochondrial DNA abnormalities may be demonstrated revealing maternal transmission. Early onset of movement disorders in children precludes reproduction and future transmission of the genes.

ATAXIAS

Congenital anomalies of the cerebellum, posterior fossa such as Chiari malformation, Dandy-Walker syndrome and its variants and encephaloceles have ataxia as the predominant presentation because of their destruction or replacement of the cerebellar structure.

Agenesis of the cerebellar vermis is associated with generalized hypotonia and decreased deep tendon jerks and the children affected usually have varying degrees of delayed milestones, mental retardation and truncal ataxia. The presentation is often seen in infancy.⁵

A familial variant of agenesis of the cerebellar vermis called Joubert disease is inherited as an autosomal recessive trait. These patients have ataxia, mental retardation, abnormal eye movements and respiratory problems especially during infancy with alternating periods of apnea and hyperpnea.

CT scan may not be useful to detect agenesis of cerebellar vermis and other congenital cerebellar disorders and MRI scans are needed to make the diagnosis.

Infections and cerebellar brain tumors are the most common causes of ataxia seen in children. The infectious causes include acute cerebellar abscess, acute cerebellar ataxia and acute labyrinthitis.

Cerebellar abscesses account for 10 to 15 percent of brain abscesses and are frequently associated with mastoiditis or chronic otitis media. A cerebellar abscess is

characterized by nystagmus, ipsilateral ataxia and dysmetria and vomiting with headache as predominant symptoms. Antibiotics of choice for cerebellar abscess are vancomycin with ceftazidime or third generation cephalosporin along with metronidazole to cover organisms from mastoid or middle ear. Surgical drainage is indicated for posterior fossa abscesses. Behavior or incoordination problems are sequel that occur in survivors.

Acute cerebellar ataxia occurs in children at 1 to 3 years following a viral illness by 2 to 3 weeks, commonly by varicella, coxsackie or echovirus, probably as a result of an autoimmune response by the cerebellum to the viral inflammation in its tissue. It is characterized by a sudden onset of truncal ataxia that may be so severe, that the child may be unable to stand, walk or sit, and horizontal nystagmus is seen in half the cases. There may be vomiting but no fever or meningeal signs, a point to differentiate from meningitis. Occasionally dysarthria may be obvious or a presenting feature preceding the ataxia by hours or days. CSF examination is usually normal initially but may show slight pleocytosis and mild rise of proteins after a few days. Most children recover completely within a few weeks to a few months but some may have residual behavioral problems, dysarthria, incoordination and ataxia.⁶ The diagnosis is made by exclusion of other acute causes of ataxia such as acute labyrinthitis that presents with otitis media, intense vertigo, vomiting, and abnormal labyrinthine function and diagnosed by cold water caloric testing.

Toxic causes of ataxia are uncommon and caused by anticonvulsants like phenytoin at levels above 30 µg/ml, or alcohol and thallium used as a household pesticide.

Brain tumors are frequently posterior fossa tumors such as cerebellar astrocytomas, medulloblastomas or ependymomas.⁷ Vomiting typically associated with headache, diplopia, nystagmus and ataxia are characteristic diagnostic criteria. The ataxia is often associated with posterior fossa tumors especially those of the cerebellar vermis that cause truncal ataxia that is heightened by sitting or standing while those of the anterior cerebellum results in a typical broad based gait. Ipsilateral extremity ataxia is diagnostic of cerebellar hemisphere tumor or pathology.

The treatment is primarily excision of the tumor, followed by radiation and chemotherapy for tumor residual. Childhood posterior fossa tumors have a good outcome with 5 years survivals of more than 70 to 80 percent if early diagnosis and complete excision are carried out.

The metabolic disorders characterized by ataxia are abetalipoproteinemia, arginosuccinic aciduria and Hartnup disease. Abetalipoproteinemia occurs in children who present as failure to thrive with ataxia, retinitis pigmentosa, muscle weakness, peripheral neuropathy, loss of joint and vibration sense, and mental retardation and show acanthocytes in a blood smear with undetectable serum vitamin E levels.

Degenerative diseases of the central nervous system are rare but important causes of ataxia as they have a poor prognosis clinically and genetically. They are ataxia telangiectasia, Friedreich's ataxia and its variants, olivopontocerebellar atrophies and rare causes of progressive cerebellar ataxia such as vitamin E deficiency related ataxia, Pelizaeus-Merzbacher disease, neuronal ceroid lipofuscinosis and GM2 gangliosidosis.

Ataxia telangiectasia⁸ is the most common of the inherited degenerative ataxias and begins at about 2 years of age progressing to loss of ambulation by adolescence. Difficulty in fixating the eyes on an object with overshooting of the target and refixating by use of lateral movement of the neck, called 'oculomotor apraxia' and horizontal nystagmus are frequently the presenting features. Telangiectasia over bulbar conjunctiva, bridge of the nose, ears and exposed surfaces of the skin over the extremities with loss of elasticity occur by 5 to 10 years of age. Abnormalities of immunological function with frequent sinopulmonary infections and up to 100-fold greater chance of developing lymphoreticular tumors as well as brain tumors are well known. Elevated alpha-fetoprotein, reduced secretory IgA, IgG2, IgG4, IgE and increased incidence of chromosomal breaks (especially Chr 14) are the laboratory abnormalities seen. Death is usually by infection or tumor dissemination.

Friedreich's ataxia is usually an autosomal recessively inherited disorder but autosomal dominant forms are also seen.^{9,10} Ataxia is slowly progressive, involving the lower extremities more than upper extremities, with positive Romberg's test, absent deep tendon jerks, extensor plantar responses, and loss of joint position and vibration sense due to involvement of posterior columns, characteristically seen beginning at about 8 to 10 years of age. Nystagmus, explosive dysarthric speech, significant distal muscle weakness with a preserved intellect, musculoskeletal abnormalities such as pes cavus, progressive kyphoscoliosis with abnormal visual, auditory brainstem and somatosensory evoked potentials help in the diagnosis.

Spinocerebellar ataxia, and its variants are similar to Friedreich's ataxia. Roussy-Lévy disease has similar features but in addition has wasting of the lower extremity muscles with a "stork-like" contour. The Ramsay Hunt syndrome has myoclonic epilepsy associated with it.

The olivo pontocerebellar atrophies^{11,12} are rarely seen in children with a dominant inheritance presenting as ataxia, cranial nerve palsies, abnormal sensory findings, nystagmus, dysarthria and seizures.

CHOREA

Sydenham's chorea is the most common acquired chorea of childhood and the only neurological manifestation of rheumatic fever.¹³ It has been known for three centuries and its association with rheumatic fever has been known

for two centuries, yet it is often misdiagnosed. It is probably caused by an autoimmune response of the central nervous system to the beta-hemolytic *Streptococcus*. A organism leading to vasculitis of the cortical arterioles, with round cell infiltration of the brain in the surrounding area, especially in the caudate nucleus, cerebral cortex and subthalamic nuclei, causing over activity of the dopaminergic system. Demonstration of beta-hemolytic streptococcal infection by culture and serology may be difficult because chorea appears several months after the infection.¹⁴ Anti-streptolysin-O titers tend to be transient and are elevated in only two-thirds of cases, other titers such as anti-DNase B and anti-NADase may be more persistently elevated. Careful cardiac auscultation, electrocardiography and echocardiography assist in diagnosis of carditis observed in one-third of patients with Sydenham's chorea. Children present with chorea, emotional lability (weeping, dysphoria and inappropriate laughter) and hypotonia. Subtle early behavioral changes (encephalopathy) and hypotonia may be severe enough to confine the child to the chair or bed. The encephalopathy may be marked by anxiety, inattentiveness and learning deterioration such that a dementing illness is suspected. The chorea is characteristically symmetric but may be unilateral with rapid jerky movements prominently seen in the face, trunk and distal extremities and are increased by stress, disappear in sleep and may fleet from one muscle group to another. Hypotonia may be disabling causing inability to feed dress or walk especially if chorea is also severe. Characteristic signs associated with Sydenham's chorea are "milkmaid's grip" caused by relaxing and tightening handshake, the "choreic hand" caused by flexion of the wrist and extension of the fingers, "darting tongue" as the tongue cannot be protruded for prolonged periods, and the "pronator sign" when the arms and palms turn outward when held above the head.

Sydenham's chorea lasts for a few months to two years and may recur within two years of remission. The treatment consists of avoidance of stress, diazepam, phenothiazines and followed by haloperidol if the former is not successful, besides penicillin prophylaxis till adulthood. Haloperidol overdose should be avoided by using a dose that does not completely suppress chorea. Valproate and steroids have been recently recommended for Sydenham's chorea. The chorea may fluctuate in severity for several months and recurrent episodes are observed in 10 percent of cases. The intellectual impairment and emotional lability persist for many years in some children, despite appropriate short-term and long-term antibiotic management, requiring appropriate educational placement and counseling.

Paroxysmal kinesogenic choreoathetosis is characterized by a sudden onset of choreoathetosis, unilateral or bilateral, or dystonic posturing of a leg or arm and associated facial grimacing and dysarthria usually lasting a few

seconds up to a minute. The condition has definite precipitating factors such as sudden movement, excitement or stress. It is seen at 2 to 14 years with several attacks daily or only an occasional attack a few months apart. There are no findings on neurological examination, EEG and neuropathology. A familial autosomal recessive inheritance is commonly noted. The drug of choice is phenytoin that can be withdrawn successfully by adulthood.¹⁵

Huntington's chorea is a rare progressive degenerative disorder of the CNS of unknown etiology and inherited as an autosomal dominant trait with the gene located on the long arm of chromosomal 4p 16.3. Although most commonly seen in mid adult life, it may begin at both extremes of life and in children as early as 5 years of age.^{16,17} About 10 percent of children present in childhood (Juvenile form) and 80 to 90 percent inherit this dominant condition from their father.¹⁸ Chromosomal imprinting involving parental gene methylation has been implicated in this genetic phenomenon. Rigidity and dystonia are more prominent in children than the chorea that involves the proximal muscles causing semi-purposeful acts in order to mask the involuntary movements. Behavioral and speech changes may precede intellectual deterioration by a number of years. General tonic clonic seizures (prominent in more than 50% of children) resistant to antiepileptic medication with cerebellar signs and oculomotor apraxia are seen frequently in children and they have a fast progression leading to death by adolescence needing proper counseling of the patient and the family. The mean bicaudate to bifrontal ratio is diagnostic on CT scan and is the neuro pathological correlate of severe atrophy of the caudate and putamen of the basal ganglia with variable neuronal loss in the frontal cortex, hippocampus and cerebellum. The cerebrospinal fluid analysis shows decreased GABA in about two-thirds of patients.¹⁹ The dopamine metabolite, homovanillic acid may be decreased in the juvenile, rigid form. Despite the genetic advances in this disorder, the cause for progressive neuronal loss is speculative ranging from an excess of excitotoxin to disturbance of growth factors for neuronal survival. There is no specific therapy for the disease and the pediatrician should provide appropriate counseling to the family of the patient. Because many juvenile onset Huntington's disease patients are genetic and rarely sporadic, a careful family history is necessary to diagnose early and to find out minimally affected family members.

The progressive intellectual and motor decline in children with Huntington's chorea is unresponsive to pharmacological treatment, seizures can be controlled by anticonvulsants and rigidity may be partially reduced by dopamine agonists. Neuroleptic agents can be used to control behavior and chorea.²⁰ Children tend to survive for a shorter time (5-10 years) than adults (10-15 years) so that they are unable to reproduce and genetically transmit the disease.

BALLISMUS

Ballismus is uncommon in children and considered by many to be a severe form of segmental or hemichorea and is usually seen in Sydenham's chorea, following encephalitis or closed head injury. The relation with vascular event involving the subthalamus is not evident in children as it is in adults. Treatment with dopamine receptor blocking agents is effective.

PARKINSONISM

Parkinsonism is characterized by bradykinesia, tremor, rigidity, and abnormal posture and is usually uncommon in children and adolescence. It is usually a minor component of a major neurological involvement due to encephalitis or head trauma, olivopontocerebellar degeneration or pallidopyramidal syndromes or a major manifestation as isolated idiopathic Parkinson's disease. The rigidity seen in continuous motor fiber activity syndromes (Issac's syndrome, neuromyotonia) need to be considered while diagnosing Parkinsonism in children. The puzzling feature of juvenile onset Parkinsonism is that the dystonia is out of proportion and prominent as compared to bradykinesia a condition recognized as 'Juvenile onset idiopathic dystonia Parkinsonism' (responding to dopamine in addition to levodopa.²¹ It is further defined as sporadic or hereditary (dominant or recessive) and with or without diurnal fluctuations (Segawa syndrome).²² Deterioration of symptoms in the evening is a pointer to the diagnosis of idiopathic juvenile dystonia Parkinsonism and many children diagnosed as dystonia that respond to dopamine belong to this category.²³ Hence, all patients with sporadic or familial dystonia, particularly with manifestations of Parkinsonism must be given a fair trial of levodopa or dopamine agonists.²⁴ In this way many children that are bedridden due to rigidity and abnormal movements can be restored to normal function including walking and running.

DYSTONIAS

Dystonia in children is a disorder of the basal ganglia and is characterized by contraction of opposing agonist and antagonist group of muscles of limb and axial musculature. Initially the dystonia is apparent with initiation of movement such as reaching for an object or walking. The forceful muscle contractions increase with anxiety, emotional situations and reduce in sleep and may be mistaken for a conversion phenomenon but later in the illness, there is obvious slow or rapid, forceful twisting movements of limbs and trunk including the head and neck characteristic of dystonia.

Retrocollis and anterocollis may be strong enough to produce fracture-dislocation of the atlantoaxial joints. Tremors may be present and enlarged affected muscles are prominently by inspection and palpation and may be the clue to the dystonic state in the absence of obvious dystonia.

In the late stages of dystonia, abnormal posturing may persist at rest deforming the body and limbs causing motor disability.

In children, as the dystonia evolves over the years, often beginning focally in the foot and becoming segmental or generalized, topographical classification is not appropriate. However, hemidystonia is a condition in which underlying structural lesions of the basal ganglia such as tumor, arteriovenous malformation or cerebrovascular accident must be ruled out by MRI scan studies.²⁵

Torsion dystonia (idiopathic dystonia musculorum deformans) is a prototype form of dystonia occurring in late first or early second decade of life.^{26,27} At rest, neurological findings may be absent and intermittent changes in gait and posturing may occur and may be confused with a psychogenic condition. The movements and posturing dissipate in sleep and are exacerbated by physical and emotional stress. Over a period of time, progression of forceful, twisting and sustained movements and posturing of the limb and trunk musculature, co-contraction of muscles producing bizarre contortions during walking (prancing) and backward walking or 'dromedary' gait on all fours may be seen. The forceful muscle contractions are painful and work hypertrophy of affected muscles are noted, producing gross deformities due to sustained muscle contractions of trunk and limbs prevent walking and sitting. Variability of progression is important to stress in counseling the parents and affected children. Variability in expression of phenotype may be linked to the uncertainty that exists whether most cases are inherited as dominant or sporadic mutations or rarely as X-linked or recessive types with improper penetrance.²⁸ No specific test exists for the diagnosis of torsion dystonia, as neuropathological studies of the basal ganglia have been unrevealing and many measures of neurotransmitters, receptors, specific enzymes and growth factors have shown no consistent defect. The diagnosis, therefore, depends on a careful family history and examination of the child and exclusion of other known causes of dystonia in children.

As the torsion dystonia evolves in a previously normal child, both physically and intellectually to a progressively deforming and debilitating condition, management can be difficult. Some patients, however, do achieve a plateau in their natural history after an initial progression especially after use of pharmacotherapeutic agents. As a first step, all patients with torsion dystonia must have a trial of levodopa, as it is the only way of distinguishing levodopa responsive dystonia - Parkinsonism. Anticholinergic agents are the mainstay of treatment as they are quite well tolerated as compared to adults. Trihexyphenidyl or other agents may be used frequently at increasingly tolerable doses. Alternatively, carbamazepine and dopamine receptor antagonists such as haloperidol or Pimozide may be useful or a combination of agents may be rarely useful. Intramuscular injections of botulinum toxin²⁹ are useful

to manage focal incapacitating aspects of dystonia such as writer's cramp, spasmodic dysphonia or torticollis. Treatment of torsion dystonia is one of the more difficult conditions to manage in pediatric neurology practice yet the role of stereotactic surgery is limited due to proper use of drugs to control it. Alternative therapies such as biofeedback, relaxation psychotherapy and acupressure – head bracing at sensitive “pressure points” have been successfully tried to control dystonia.

Other Causes of Dystonia

The other forms of dystonia are more common and require specific treatment as compared to the conventional gold standard of torsion dystonia used for comparison. Transient, intermittent, persistent or progressive dystonias may be seen in infancy. Abnormal twisting postures of arms, legs or tongue may appear in the first few months of life and resolve completely in several years called ‘Transient dystonia of infancy.’³⁰ Spasmus nutans in infancy is characterized by head tilt that is prominent and persistent and may be the only early manifestation till associated head nodding and nystagmus appear as a classic triad.

Torticollis is relatively common in infancy and may be due to short sternocleidomastoid with or without a tumor, bony and ligamentous abnormalities of the atlantoaxial joint, posterior fossa tumors and upper lobe pneumonia. Retrocollis may be seen in some conditions such as retropharyngeal abscess or severe cardiorespiratory distress.

A condition called paroxysmal infantile torticollis is seen in infants with intermittent torticollis lasting for a few minutes to hours or a few days and recurring every few months. It is important to exclude intermittent dislocation of the neck as a cause of paroxysmal torticollis by doing a routine neck and craniocervical X-ray examination.

Another common cause of transient dystonic state in children is an abnormal sensitivity to medications especially neuroleptics such as haloperidol, pimozide or fluphenazine and antiemetics or antihistaminics. Metoclopramide is well known for its production of oculogyric crises, trismus, neck rigidity, dystonia and abdominal board-like rigidity in a dyskinetic extrapyramidal reaction. A rapid response to oral or parenteral anticholinergic medication (diphenhydramine) is both diagnostic and therapeutic.³¹ Acute dystonic reactions to high doses of phenytoin and carbamazepine are uncommon and are related to high serum levels of the antiepileptic medication.

Paroxysmal dyskinesias may begin in childhood or adolescence with dystonia as the prominent manifestation with abnormal movements resolving in sleep, although occasionally paroxysmal dystonia may be seen during sleep. The observation that consciousness is maintained throughout the episode differentiates it from seizures.

Kinesogenic dystonia or chorea, already been mentioned above, responds well to phenytoin or carbamazepine. A non-kinesogenic form of choreoathetosis can

begin in childhood, and dystonic posturing occurs sometimes focally, in a previously normal or neurologically impaired child with cerebral palsy or mental retardation. There is no loss of consciousness, the episode lasting for minutes to hours with normal electroencephalograms and responding well to anticholinergic medication, showing no response to antiepileptic drugs.

A perplexing condition is that of dystonia in a child with hemiplegic cerebral palsy, often starting focally as new abnormal movements (dystonia and tremor) in the affected limb, and progressing to limitation in an already handicapped limb. These movements may reach a plateau and may be difficult to treat but standard management of dystonia should nevertheless be tried. Neuroradiological studies do not show demonstrable reason for the progression but evidence of the static deficit leading to cerebral palsy.

The most common treatable dystonic condition,³² often not considered, is probably the Sandifer's syndrome. There is gastroesophageal reflux (excluded by pH probe and radiological studies) and failure to thrive, intermittent or persistent opisthotonus, retrocollis and torticollis, and behavioral instability. The children are generally mentally retarded, with a history of repeated chest infections but occasionally regurgitation and vomiting may not be prominent, the condition further confused by the dystonic reaction to metoclopramide used. The condition is often confused with choreoathetoid cerebral palsy or a progressive neurodegenerative disorder but responds well to medical or surgical treatment of the gastroesophageal reflux with both social and physical improvement in development.

Occasionally, acquired dystonia may be seen as a sequel of any of a number of conditions including infections (meningitis, encephalitis, tubercular meningitis, acquired immunodeficiency syndrome), head trauma, hypoxic ischemic encephalopathy (near drowning, burn encephalopathy), cerebrovascular event (acute hemiplegia of childhood) tumors (gliomas, craniopharyngiomas) and hydrocephalus. The dystonia may occur as a delayed onset after the obvious neurological manifestations of the original brain insult.

Rare, genetic and metabolic disorders affecting the central nervous system may involve the basal ganglia and produce movement disorders in children and adolescents. Wilson's disease, a recessive disorder of copper metabolism must always be excluded by looking for the K-F ring (by a slit-lamp examination of the Descemet's membrane in the eyes) and by blood and urine studies.

Hallervorden Spatz disease,³³ a recessive, degenerative disorder affects basal ganglia producing dyskinetic movements like dystonia and rigidity with dysarthria and dementia with iron deposits in basal ganglia regions demonstrable on neuroimaging.

Some disorders of genetic or metabolic causes produce progressive dystonia, recurrent coma and seizures such as neuronal ceroid lipofuscinosis (electron microscopy of skin, sweat glands or rectal mucosa) hexosaminidase deficiency, mitochondrial cytopathies (Leber's optic atrophy, Leigh's disease, and Kearns-Sayre syndrome), aminoacidopathies (classical phenylketonuria), Rett's syndrome,³⁴ neuroacanthocytosis (blood film acanthocytes) and several organic acidemias (blood gases, blood pH, leukocyte enzymes) need to be recognized.

Tremors

Tremors are rhythmic, oscillatory, involuntary movements observed at rest or with movement. They are common in children and are a benign form of movement disorder, as Parkinsonism with resting tremor is uncommon in children, most being related to an activity such as maintaining a posture (static) or a motor task (kinetic). It is common to note an exaggerated tremor due to sympathomimetic drugs for asthma or to antiepileptic drugs (valproate or carbamazepine), occasionally incapacitating enough to change treatment.

A fine tremor denoting high anxiety or exaggerated physiologic tremor is much more commonly seen.

Benign essential tremor, which is classically intentional, is a common cause of tremor in children and may be a chance finding during a neurological examination for another reason. It is transmitted as autosomally dominant and a family history is often positive. Head nodding, vocal tremor, and severe body tremors while standing (orthostatic) are seen and need counseling of the parents and occasionally beta-adrenergic blocking agents such as propranolol or metoprolol and vocational guidance (avoidance of artistic, musical and architectural and other careers needing fine motor coordination). Other causes of tremors are unusual like wing beating tremor of Wilson's disease, tremors following closed head injuries, acute (Guillain-Barré syndrome), subacute or chronic (Charcot-Marie-Tooth syndrome and Roussy-Lévy syndrome with a possible contiguous gene defect between the two) and the tremor of infantile tremor syndrome.

The Gilles de la Tourette's syndrome is a lifelong condition having a prevalence of 1:2000 presenting between 2 and 21 years of age and inherited as autosomal dominant the gene having mapped to chromosome 18q 22.1. The syndrome is characterized by motor tics, vocal tics, obsessive compulsive behavior, and attention-deficit disorder with hyperactivity, not all of which may be present in a single patient, the symptoms waxing and waning and exacerbated by stress and anxiety. The severity of the disorder can be usually determined from the severity of symptoms during adolescence. Medication should be considered when the motor tics or vocalizations interfere significantly with the child's social and academic interactions. Although

the management is largely multidisciplinary and behavior and biofeedback programs are successful in some patients, Haloperidol 0.25 mg/day increased weekly by 0.25 mg till 2-6 mg/day, penfluridol, pimozide, clonidine (0.05 mg/day increased to 0.0125/day) may be useful. However, a close watch for the side effects of the medication is necessary. Stimulant medication such as methylphenidate is a common cause of Tourette-like symptoms and all children receiving it must be closely monitored.

A tropical disorder, of obscure variety, affecting infants from 6 to 18 months, characterized by coarse tremors, regression of motor and mental milestones and anemia, accounting for 0.2 to 1 percent admissions in developing countries is called the infantile tremor syndrome.³⁵ It is a diagnosis of exclusion when hologram, bone marrow, CSF examination, chest radiogram are found to be normal. The proposed etiological theories nutritional, degenerative or infective and treatment consists of blood transfusion for severe anemia, treatment of intercurrent infections on war footing, and iron, folate, vitamin B₁₂ supplementation and occasional use of phenobarbitone for severe tremors.

Myoclonus

Myoclonus is a brief, involuntary contraction of a muscle or group of muscles producing regular, often irregular movements at a joint such as fingers and toes, wrists elbows, hips and orofacial musculature, at rest or in response to a tactile, aural or visual stimulus.

Myoclonus is a common manifestation of preterm newborns and can be difficult to distinguish from fragmentary neonatal seizures except when it is clinically associated with opsoclonus. Perinatal injury and metabolic disturbances (hypoglycemia, hypoxia, hypocalcemia) should be considered, however, in most neonates the opsoclonus is transient with a normal neurological development.³⁶ Many children have sleep myoclonus while falling asleep (hypnagogic) or on awakening. Benign myoclonus of infancy³⁷ is difficult to differentiate from infantile myoclonic epilepsy (West's syndrome) because the clusters of myoclonic jerks are similar but in the former the serial electroencephalograms and neurological outcome are normal, the myoclonic clusters disappearing by 2 years. Myoclonic movements on awakening may be a prominent feature of Juvenile myoclonic epilepsy of Janz,³⁸ the myoclonic jerks preceding generalized seizures, usually with a positive family history in two-thirds and polyspike waves at 3 to 4 Hz on the electroencephalograms. Myoclonic dystonia is a distinct syndrome of an autosomal dominant disorder giving rise to a combination of 'lightning jerks' associated with dystonic postures and spasms, characteristically resolved by alcohol, and needs to be distinguished from hereditary essential myoclonus and benign hereditary chorea.³⁹

Symptomatic myoclonus may be associated with a previous hypoxic or hypoxic-ischemic event or be one of several neurological manifestations of a multisystem disorder

such as neuronal ceroid lipofuscinosis (neuraminidase deficiency), Lenora body inclusion disease, mitochondrial cytopathy, subacute sclerosing panencephalitis and multiple system atrophy (Ramsay-Hunt syndrome). Most of these disorders are characterized by progressive cognitive decline and behavioral change and require specific investigations. Mitochondrial encephalomyopathy⁴⁰ accounts for a substantial proportion of cases of progressive myoclonic ataxia. Muscle biopsy shows presence of ragged red fibers in most patients, a syndrome called myoclonic epilepsy with ragged red fibers (MERRF). A mutation of mtDNA at position 8344, detectable in leukocytes, is common in the syndrome with cortical reflex myoclonus, occasional tonic clonic seizures and ataxia. Other variable features include muscle weakness, deafness, optic atrophy, dementia, lipomas and peripheral neuropathy, maternal relatives having monosymptomatic varieties or the full MERRF phenotype.

The opsoclonus-myoclonus syndrome or myoclonic encephalopathy of infancy is rare. The onset is of a subacute severe myoclonic jerking of the head and trunk especially while sitting usually requiring support, with a rapid flurry of conjugate eye movements in different directions, known as opsoclonus. The disorder represents a more severe form of acute cerebellar ataxia of childhood usually following encephalitis. With a history of prior viral (varicella) exanthem and cerebrospinal fluid showing mononuclear pleocytosis and high protein levels. Most children recover completely over days, weeks or months but some children have persistent ataxia, with intermittent worsening during intercurrent infections and neurocognitive and behavioral impairment. A course of oral steroids or ACTH is justified in children with persistent findings. Rarely opsoclonus-myoclonus may be caused by neural crest tumors (neuroblastoma or ganglioneuroblastoma) and persistence of symptoms is an indication for a magnetic resonance imaging of the abdomen to rule out the tumor that can be surgically completely removed.⁴¹

Startle Syndromes

The Startle syndromes are heterogeneous with confusion between the normal startle response, other 'jumps' or 'starts' that may resemble startle or even stimulus sensitive myoclonic or epileptic events.

Hereditary hyperekplexia^{42,43} consists predominantly of an exaggerated startle response. Inheritance is autosomally dominant with variable expression. The disorder presents in infancy with increased tone, which may be enhanced by handling (the stiff baby syndrome). On first waking the children have momentary attacks of generalized muscle stiffness and loss of postural control following startle, and a broad-based gait. They exhibit an exaggerated motor response to many stimuli, including tapping the body or loud noise representing an exaggerated startle response (and may be associated with echolalia or coprolalia in syndromes such as Jumping Frenchman of Maine,

latah and myriachet). The disorder tends to progress over many years although it can fluctuate. The disease locus was linked to chromosomal 5 and recently shown to be the $\alpha 1$ subunit of the inhibitory glycine receptor.

Neuromuscular Disorders in Children: A Clinical Approach for the Pediatricians

Nitin Maheshwari

A wide variety of neuromuscular conditions present in childhood. They all have their different way of presentation. However, some of them may share some features. These neuromuscular conditions may be genetically determined or non-hereditary, congenital or acquired, acute or chronic, and progressive or static. As specific therapy is available for some of these conditions, and because of genetic and prognostic implications, precise diagnosis is important. This review discusses an approach to diagnose neuromuscular conditions in clinic practice.

The term neuromuscular disorders refers to disorders of the “motor unit” and specifically exclude supra-segmental disorders like cerebral palsy. The motor unit consist of four components:

- A motor neuron in the brainstem and anterior horn cells of the spinal cord
- Its axon together with other axons, forms the peripheral nerve
- The neuromuscular junction
- All muscle fibers innervated by single motor neuron.

On the basis of this basic anatomy, neuromuscular disorders can be classified into various groups like primary muscle disorders, primary nerve disorders, disorders of neuromuscular junction and disorders of anterior horn cells (Table 1). The classification on the basis of genetics exists as well. Many clinically defined entities are genetically heterogeneous. However, as most of the genetic tests are not readily available in India, the anatomical classification remains the most useful one, in practice.

This review outlines a diagnostic approach for neuromuscular conditions in clinical practice. An approach to diagnose and investigate “floppy infant” is not included here. No attempt is also made to describe each neuromuscular condition. The review outlines presenting features, salient points in history taking, clinical examination, role of investigations and finally a diagnostic algorithm for

Table 1: Anatomical approach to neuromuscular conditions

Disorders primarily affecting muscles

Muscular Dystrophies

- X- linked (Duchenne, Becker, Emery-Dreifuss)
- Autosomal (Facioscapulohumeral, Limbgirdle)
- Congenital muscular dystrophies

Myopathies

- Congenital (central core, multicore, nemaline rod, myotubular)
- Metabolic (glycogenoses, lipid disorders, oxidative phosphorylation and mitochondrial)
- Inflammatory myopathies (Dermatomyositis, inclusion body myositis)

Myotonic syndrome

- Myotonic dystrophy, myotonia congenital, paramyotonia congenita

Disorders of neuromuscular junction

Myasthenic syndromes

- Congenital, transient neonatal and juvenile myasthenia, lambert eaton syndrome

Disorders primarily affecting nerves

Hereditary

- HMSN (CMT), HMSAN

Acquired

- Guillain-barre (AIDP), CIDP, toxic metabolic, endocrine (hypothyroidism)

Disorders of anterior horn cells

- Spinal muscular atrophy
- Poliomyelitis

pediatricians for clinic practice. Principles of management are also discussed in brief.

PRESENTING FEATURES

Neuromuscular conditions can present with wide variety of symptoms (Table 2). Most of the children present in early childhood with symptoms like frequent falling, toe

Table 2: Presenting features of neuromuscular conditions in children*Non-specific symptoms*

- Weakness
- Frequent falls
- Clumsiness

Symptoms due to lower limb involvement

- Abnormal gait, i.e. waddling gait
- Toe walking
- Difficulty in climbing stairs
- Difficulty in getting up from sitting or lying position
- Swelling of calf muscles

Symptoms due to upper limb and back involvement

- Difficulty in elevation of arm
- Difficulty in combing hairs, dressing or undressing
- Weakness of hand grip
- Change in handwriting
- Pain in hands following prolonged writing

Symptoms due to head face and neck involvement

- Double vision, drooping of eyelids
- Difficulty in swallowing chewing, sucking, whistling
- Change of voice
- Floppy neck

walking, clumsiness and difficulty in getting up from floor. Some of them present with inability to do normal jumping or hopping. A good proportion of them have reportedly normal motor milestones. However, in retrospect some of them may have definite delayed motor milestones. Primary muscle disorders have proximal distribution of muscle weakness and wasting and symptoms may include abnormal gait, difficulty in getting up from floor, difficulty in elevating arms or combing hair.

Primary nerve disorders present with distal distribution of muscle weakness and wasting and symptoms may include weak hand grip or pain in hands after prolonged writing. Excessive foot arch, abnormalities of sensations, limb pain may be the presenting feature of some. Generally speaking muscular disorders are more common than primary nerve disorders.

Metabolic myopathies are relatively uncommon but may present with multisystem involvement. Conditions affecting neuromuscular junction presents with fatigable weakness, like progressive drooping of eyelid as the day progresses. In recent years many congenital myasthenic syndromes have also been described. Diagnosing them could be a challenge. These disorders may present with ptosis, reduced eye ball movements (ophthalmoplegia) and difficulties in feeding, swallowing and chewing in first couple of years of life.

HISTORY

Apart from an understanding of the presenting complaints, a detailed history is also essential to reach to an appropriate diagnosis. The history should include antenatal history, birth history, family history and developmental history.

Polyhydramnios and reduced fetal movements are one of the earliest indicators of neuromuscular weakness in fetus. Arthrogryposis, undescended testicles, talipes and history of choking whilst feeding may also be suggestive of neuromuscular weakness in newborn period. A history of similar disorder in other male members of family suggests X linked recessive pattern of inheritance like in DMD. A child with suspected myotonic dystrophy may have a mildly affected mother. A good proportion of neuromuscular conditions are associated with developmental delay. Few children may have reportedly normal milestones. However, in retrospect some of them may have definite delayed motor milestone.

EXAMINATION

A proper exposure is essential for a comprehensive examination of the child. It is always helpful to observe the child in different postures and positions (sitting, standing and walking). Making a video recording of the gait and analysing it with the physiotherapists or other experts in team may be of help. Examination of the neuromuscular system should include assessment of the muscle bulk, tone, strength, deep tendon reflexes and sensory examination. Tongue should also be examined for presence of fasciculations. Table 3 outlines some salient features of examination which may help in distinguishing primary nerve and muscle disorders.

Proximal distribution of muscle weakness is seen in primary muscle disorders like myopathies and muscular dystrophies with an exception of myotonic dystrophy. Primary nerve disorders usually present with a distal distribution of muscle weakness with reduce or absent deep tendons reflexes. Fasciculations of muscle, which are best seen on the tongue, are a sign of denervation and seen in conditions like spino muscular atrophy (SMA). Sensory abnormalities indicate neuropathies. Fatigable weakness is characteristic of neuromuscular junction disorders like myasthenia. Myotonia is specific for condition like myotonic dystrophy. Examination of the parents may be helpful in certain situations. Mother should be examined for evidence of myotonia when suspecting myotonic dystrophy. Similarly, parents should be examined for presence of pes cavus when hereditary neuropathies are suspected.

INVESTIGATIONS

A careful clinical examination in conjunction with good history is usually sufficient to make a distinction between

Table 3: Examination findings which may help in distinguishing nerve and muscle disorders*Features indicating primary muscle disorder*

- Proximal distributions of weakness and muscle wasting
- Preservation of deep tendon reflexes (although, may be diminished)
- Calf muscle hypertrophy (Especially DMD)

Features indicating primary nerve disorder

- Distal distribution of weakness and muscle wasting
- Absent or diminished deep tendon reflexes
- Fasciculations: best seen over tongue
- Sensory abnormalities may be present
- Pes cavus

Features not helpful distinguishing between primary nerve and muscle disorders

- Muscle pain or myalgia: can be present in both
- Muscle contractures: can be present in both

Features indicating neuromuscular junction involvement

- Fatigable weakness

primary nerve and muscle disorder. A diagnostic algorithm is provided here to help clinicians in selecting investigations thereafter. In few cases, history and examination may not be enough to differentiate between primary nerve or muscle disorders. In these cases a combination of tests or repeating the same test again may be needed. Brief details of commonly required investigations are given here (Table 4).

- *Serum creatinine phosphokinase:* Severe lysosomal enzymes are released by damaged or degenerating muscle fibres and may be measured in serum. The most useful of these is the creatine phosphokinase (CPK), which is found in only three organs and may be separated into corresponding isozymes: MM for skeletal muscle, MB for cardiac muscle, and BB for brain. The serum CPK is by no means a universal screening test for neuromuscular disease because many diseases of the motor unit may not be associated with elevated enzymes. However, the CPK is characteristically elevated in certain conditions like duchenne muscular dystrophy (DMD).
- *Nerve conduction studies:* Motor and sensory nerve conduction can be measured electrophysiologically by using surface electrodes. In clinical practice, three parameters are routinely measured; amplitude, conduction velocity and latency. On the basis of those demyelinating conditions can be differentiated from conditions with primary axonal involvement. Neuropathies of various types can also be differentiated. The site of a traumatic nerve injury may also be localized.

Table 4: Investigations*Commonly required*

- Serum creatinine phosphor kinase (CPK)
- Nerve conduction studies
- Muscle biopsy
- Genetic Studies

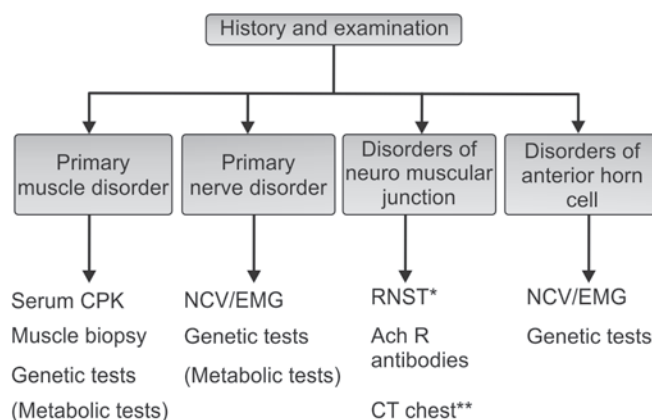

Uncommon required

- Electromyography (EMG)
- Nerve biopsy
- Metabolic investigations

- *Muscle biopsy:* The muscle biopsy is the most important and specific diagnostic study of muscle. Not only are neurogenic and myopathic processes distinguished, but also the type to myopathy and specific enzymatic deficiencies may be determined. The muscle biopsy usually can be done under local anesthesia if the child is big enough to cooperate. However, some young children may require general anesthesia for this. The vastus lateralis (quadriceps femoris) is the muscle that is most commonly sampled. The deltoid muscle should be avoided in most cases. Certain centres are also preferring to do needle biopsies in selected cases, which can be done on outpatient basis.

Histochemical studies of frozen section of the muscle are obligatory in all pediatric muscle biopsies, because many congenital and metabolic myopathies cannot be diagnosed from paraffin section using conventional histologic stains. Immunohistochemistry is useful supplement in some case such as for the demonstration of dystrophin in suspected muscular dystrophy. A portion of the biopsy should be fixed for potential electron microscopy, but ultra structure has additional diagnostic value only in selected cases. Muscle biopsy interpretation is complex and should be done by and experienced pathologist only.

- *Electromyography (EMG):* EMG is less useful in pediatric practice than in adult medicine, in part because of technical difficulties in recording young children and in part because the best results require patient cooperation which is usually not possible from small kids. In the present era, EMG is usually done only if the diagnostic dilemma persists, despite performing other investigations.
- *Genetic tests:* A spectacular development has taken place in field of genetic testing for neuromuscular conditions in last decades or so. Many genetically diverse neuromuscular conditions with similar clinical presentation have been identified. In recent years, genetic tests for common conditions like DMD, HMSN, and SMA have become available in India. Diagnosis of conditions like DMD can be confirmed by performing genetic tests directly, without going for muscle biopsy

Flow chart 1: Diagnostic approach to a child with suspected neuromuscular condition

*Repetitive nerve stimulation test

**Should be considered when suspecting autoimmune myasthenia

if clinical examination and history is consistent with the diagnosis.

A careful selection of investigations is important and at the same time certain diagnostic pitfalls must be avoided. Some practical points to remember include that a single CPK measurement does not necessarily rule out muscular dystrophies. A child, who clinically appears to have a muscular dystrophy but has normal CPK level, should be investigated for myopathies. Electromyography (EMG) is technically difficult to perform in children, and results of this should always be interpreted with caution keeping in mind the false positive and negatives. Nerve biopsy is rarely needed nowadays, as genetic tests to diagnose common neuromuscular conditions like DMD, HMSN, SMA are available in India (Flow chart 1).

PRINCIPLES OF THE MANAGEMENT

A multidisciplinary approach is required to provide appropriate care to children with neuromuscular conditions. Although majority of them do not have any specific drug treatment, some of them do have definitive treatment like pyridostigmine in myasthenia. Steroids are of proven value to increase the ambulatory period, heart and lung function in children with DMD. A pediatrician or neurologist

should help in coordinating the care/ inputs from different specialities.

- Physiotherapy—stretches aimed at prevention of contractures
- Occupational therapy—appliances, improvement of posture and function, facilitating activities of daily living
- Evaluation and treatment of associated cardiac dysfunction
- Respiratory support—assessment of requirement for invasive or noninvasive ventilation and or tracheostomy
- Orthopaedic intervention in setting of established or evolving joint contractures, prevention and correction of scoliosis
- Encouragement of overall development and stimulation of learning
- Prevention (influenza and pneumococcal vaccination) and prompt treatment of respiratory infections.

CHAPTER 123

Acute Bacterial Meningitis: Issues and Controversies

S Aneja, Anju Aggarwal

INTRODUCTION

Acute bacterial meningitis (ABM) is an important cause of mortality and morbidity in children in developing countries. In a multicentric survey in India, ABM constituted 1.5 percent of admissions in pediatric wards and the mean case fatality was 16 percent.¹ Even though the mortality due to this disease has decreased over the years with the availability of potent antibiotics, a significant number of patients are left with neurological sequel.²

EPIDEMIOLOGICAL ISSUES—DEVELOPED VERSUS DEVELOPING COUNTRIES

Any organism can potentially cause meningitis. Causative agents of ABM vary with age, immune system and immunization status of the patient. During the first 2 months of life, *Escherichia coli* K1 and other gram-negative enteric bacilli, *Streptococcus agalactiae* and *Listeria monocytogenes* are the usual offending organisms. In children between 2 months and 12 years, bacterial meningitis is primarily due to *H. influenzae* type b (Hib), *Streptococcus pneumoniae* (Sp) and *Neisseria meningitidis* (Nm). In children with severe malnutrition, compromised immunity or anatomical defects, infection can occur with other microbes like *Staphylococcus*, *Salmonella*, *Pseudomonas*, etc. Reports from developing countries indicate Hib and Sp account for most of the cases though a sizeable proportion of cases presumed to be bacterial in nature fail to demonstrate any pathogen.³

The widespread use of conjugate vaccine against *Haemophilus influenzae* type b in many developed countries has lead to marked decline in number of cases of meningitis. However, it remains a significant pathogen in resource poor countries. Hib is widely given to infants of the affluent population in India as well. There is no data to demonstrate the decline in incidence of meningitis in this group after change in immunization practices. In

countries with routine Hib vaccination, the median age of ABM has shown an increase with proportionately more cases occurring in adults.⁴ This trend is likely to continue after initiation of routine immunization with conjugate pneumococcal vaccine in many developed countries. Sp colonizes the upper respiratory tract of healthy individuals. However, disease often is caused by a recently acquired isolate. Of the 84 serotypes of Sp, serotypes 1, 3, 6, 7, 14, 19, and 23 are the ones most often associated with bacteremia and meningitis. Transmission is person-to-person, usually by direct contact, and secondary cases are rare.

Most cases of ABM are sporadic except meningococcal meningitis, which often occurs in epidemic form especially in sub-Saharan Africa and Indian subcontinent. Meningococcal meningitis occurs most frequently in young children with peak attack rates in 6 to 12 months infants. A second peak occurs in adolescence. Clusters of meningococcal disease among adolescents and young adults have been reported with increasing frequency in the last decade. Disease rates in adolescents are high because this age group has the highest rate of carriage of *Meningococcus*.⁵

CLINICAL FEATURES

Early symptoms of meningitis in young children are often vague and ill-defined. In general, younger the infant the more nonspecific are the symptoms. History suggestive of upper respiratory infection may be noted in nearly 75 percent of patients. The main symptoms, which are highly suggestive of a diagnosis of ABM in infants are fever (with or without vomiting), alteration of behavior (infant becomes lethargic or drowsy, irritable, feeds poorly), a high-pitched cry, seizures and a full or tense anterior fontanelle. Specific signs of meningeal irritation may not be seen in infants. In older children, classical signs and symptoms of meningitis like fever, headache, vomiting, photophobia, neck stiffness and the meningeal signs are likely

to be present. Neck stiffness is the most important of all meningeal signs and is seen in 50 to 90 percent of patients. Kernig sign and Brudzinski sign are other meningeal signs. The meningeal signs are due to reflex muscle spasm in reaction to pain on stretching of contents of spinal cord. These signs may be absent in comatose patients.

The second mode of presentation is acute and fulminant in which manifestations of sepsis and meningitis develop rapidly and are associated with severe brain edema and raised ICP. This type of presentation is seen most often with *N. meningitidis*. Petechial hemorrhages appearing on the skin which rapidly coalesce producing areas of purpura are considered hallmark of this disease, although they may be seen in meningitis due to other organisms also.

Seizures occur in about 30 to 40 percent cases of ABM. Alterations of mental status and reduced level of consciousness is common and may be due to increased intracranial pressure (ICP), cerebritis or hypotension. Papilledema is uncommon in uncomplicated acute meningitis and when present suggests a more chronic process such as presence of intracranial abscess, or subdural empyema. Focal neurologic signs may be due to vascular occlusion, subdural collection or cortical infarction. Overall 14 percent of children of bacterial meningitis have focal neurological signs.²

Complications

Complications of ABM can develop early in the course of illness or later after several days of therapy or may be noticed on follow-up.

Systemic Complications

Peripheral circulatory failure is a sudden life threatening complication of meningitis occurring most commonly with meningococcal infection but can accompany other type of infections. About 15 percent children with Sp meningitis have been reported to present with shock.⁶ Antibiotic therapy may initially aggravate hypotension, hence intensive monitoring is required in the initial period.⁷ Other manifestation of acute bacterial sepsis may be seen such as coagulopathy, acidosis and hypoglycemia.

Pneumonia, pericarditis and arthritis occur occasionally. Prolonged fever (>10 days) is seen in some cases due to intercurrent viral infection, secondary bacterial infection, thrombophlebitis or a drug reaction. Secondary fever that is seen after an initial afebrile period is usually due to nosocomial infection. Syndrome of inappropriate antidiuretic hormone secretion (SIADH) has been reported to occur in 28 percent of cases of ABM.⁸ It leads to cerebral edema and hyponatremic seizures.

Neurological Complications

Increased intracranial pressure (ICP) is present in almost all cases of ABM initially though only 1 to 3 percent of

cases have persistent hydrocephalus.⁹ Raised ICP as a complication of ABM should be anticipated and treated promptly. When ICP is very high, herniation of brain tissue may occur at the incisura or at foramen magnum and may lead to sudden respiratory arrest and death. Cerebral herniation following LP is an important contributor to overall mortality.¹⁰ LP should therefore, not be done in children with clinical evidence of raised ICP.

Seizures occur in about 30 to 40 percent of children with meningitis. Generalized seizures occurring within first four days are of no prognostic significance. Seizures that present after 4th days and those that are difficult to treat and those that appear late in the course of meningitis are associated with poor prognosis. Children with focal convulsions are more likely to have neurologic sequel of meningitis. Causes of late onset seizures include cerebritis, subdural effusion, vascular thrombosis and abscess formation.

Subdural effusions develop in 10 to 30 percent of patients with meningitis and are more common in *H. influenzae* meningitis. These effusions are mostly asymptomatic. Effusions usually resolve spontaneously and aspiration is required only in case of increased ICP or a depressed consciousness. Subdural empyema requires more aggressive treatment in form of aspiration.

Transient cranial nerve dysfunction and motor deficits may be seen during acute phase of illness. Hearing loss is the most common sequel of ABM. Nearly 10 to 25 percent of cases of survivors are left with permanent sensorineural loss.^{2,11} All patients of ABM should have audiologic evaluation after recovery.

Diagnostic Issues

The diagnosis of ABM is based on documenting inflammatory response of meninges (e.g. CSF cell count, protein, sugar) and on tests that demonstrate the specific causative bacterial agent in CSF (Gram's stain, culture, tests for bacterial antigen/RNA). Since the clinical features of ABM are nonspecific, especially in infants LP should be performed whenever there is suspicion of meningitis. Occasionally, LP may have to be postponed due to cardiorespiratory compromise, signs of increased ICP and infection at the LP site. In case LP is deferred, empirical antimeningitic treatment should be started after taking blood culture.

CSF Examination

CSF examination includes a naked eye examination, pressure, microscopy—total and differential leukocyte count, Gram stain, estimation of proteins and glucose and CSF culture. The CSF should be examined immediately after doing the LP since the cell count tends to fall over a period of time and may be falsely low after 30 to 60 min. The normal CSF of children contains less than 6 WBCs/mm³ and in 95 percent of cases there are no polymorphonuclear (PMN)

leukocytes.¹² Hence, presence of more than a single polymorphonuclear leukocyte in a child over 6 weeks of age is suggestive of ABM. However, CSF lymphocytosis may be a predominant feature in 10 to 13 percent of cases.¹³ CSF lymphocytosis is believed to represent an early phase of infection and repeat CSF examination in these cases will show a PMN predominance. Prior antibiotic therapy also results in lymphocytosis. Protein in CSF is raised (normal value 40 mg/dl after 2nd month of life) in all cases of ABM. In patients of ABM, CSF glucose and ratio of CSF to blood glucose (normally about 66 percent) are low.

Gram stain of the smear is one of the most simple, cheap and rapid diagnostic bedside tools useful for detection of etiological organism. In a series of pneumococcal meningitis Gram stain of CSF was positive in 90 percent cases. Centrifugation of CSF increases the positivity. CSF culture provides a confirmatory evidence of ABM and is essential for selecting appropriate antibiotic for the etiological organisms. The rate of bacterial isolation is affected by antibiotic use prior to lumbar puncture, further rate of isolation is increased if direct plating of CSF is done at bedside.

Interpreting a Traumatic Spinal Tap

In case LP is traumatic, it is recommended to do the cell count and then lyse RBCs with acetic acid and repeat cell count. The ratio of WBCs to RBC's (normal 1:500 to 1:750) can give some indication of the total cell count though it is rather cumbersome. Besides, the biochemical parameters and the Gram stain and culture are not affected by blood in CSF. About 1,000 RBCs/mm³ raise CSF proteins by 1 mg/dl.⁷ Cerebrospinal fluid from a traumatic LP should, therefore be interpreted on a combination of factors.

Value of Rapid Diagnostic Tests

Various rapid diagnostic tests including counter immunoelectrophoresis (CIE), latex particle agglutination (LPA), and enzyme-linked immunosorbent assay (ELISA) are used to detect bacterial antigen. Of these the results of CIE and LPA can be available within 1 to 2 hours but ELISA takes a longer time. LPA is more sensitive than CIE. The sensitivity of CIE can be improved by screening multiple body fluids. LPA kits are commercially available for detecting antigen of Hib, Sp, and Nm group B streptococcus and *E. coli*. A negative test for bacterial antigen cannot exclude bacterial meningitis since these tests are limited to a few specific pathogens. Due to high cost these tests should be reserved for patients who have received antibiotics and those in whom Gram's stain is negative.¹⁴

PCR of CSF has been employed to detect microbial RNA in patients with ABM. Primers are available for simultaneous detection of the common organisms. PCR-based detection of Nm antigen in CSF has been found to be useful in patients with meningococcal disease who have been pretreated with antibiotics as bacterial DNA remains in CSF 2 to 3 days after treatment.¹⁵ PCR has shown promise as

a prognostic test as well. A recent study using quantitative PCR on blood revealed that meningococcal bacterial DNA load correlates with disease severity and that the maximum load is highest in those who die.¹⁶ A broad range PCR for 16S ribosomal RNA has been used to confirm the presence of bacteria in CSF.¹⁷ Another promising development is a Gram stain specific-probe based real time PCR using 16 S ribosomal RNA which allows simultaneous detection and discrimination of clinically relevant gram-positive and gram-negative bacteria directly from blood samples.^{17a} However, at present PCR cannot be used routinely because of high cost and need for special laboratories.

Various nonspecific markers of inflammation such as C-reactive proteins, serum procalcitonin, CSF lactate, CSF CPK, TNF- α , interleukins have been investigated to differentiate bacterial meningitis from aseptic meningitis and as markers of severity of ABM with relation to outcome.¹⁸ Recently it has been shown that CSF concentration of both IL-6 and IL-8 are increased in the presence of meningeal inflammation, IL-8 could be an important tool to differentiate ABM from aseptic meningitis.^{18a}

Despite advancements in lab techniques routine culture of CSF, blood, and Gram stain of CSF remain the standard methods of establishing the etiological agent of ABM. LPA and PCR-based tests are useful in patients pretreated with antibiotics. The molecular method can also be helpful in identifying the genotype of Nm in outbreak situation.

Blood Culture

Blood Culture is positive in a 2/3rd cases of ABM and should be done in all cases. It is especially useful in cases in whom LP cannot be done or is traumatic.

Smear of petechial lesion (if present) after puncture with a lancet should be made and subjected to Gram stain to see for Nm.

Should LP be repeated in all Cases?

If LP was deferred on admission it should be reconsidered after the patient is stable and attempt made to demonstrate organism on Gram stain or by LPA. A repeat spinal tap is not indicated in most of the cases of ABM. It should be done in case of poor clinical response to therapy of 48 to 72 hours, persistent fever, unusual etiological organism or suspicion of resistance, e.g. Sp. Similarly, end of therapy LP is not routinely required if the patient is well and afebrile for preceding 5 days.¹⁹ Examination of the CSF at the end of treatment has not proven helpful in predicting relapses or recrudescence of meningitis.

Which Patients with Suspected Bacterial Meningitis should Undergo CT of the Head prior to Lumbar Puncture?

Complications associated with lumbar puncture are variable, ranging from mild alterations in comfort to

life-threatening brain herniation, which may occur in the patient with elevated intracranial pressure. After lumbar puncture, there is normally a mild, transient lowering of lumbar CSF pressure as a result of removal of CSF. In patients with raised intracranial pressure, there is a relative pressure gradient with downward displacement of the brain that can be increased by lumbar puncture, thereby precipitating brain herniation. In a study of 302 infants and children with bacterial meningitis, brain herniation developed in 6 percent of patients, occurring within 8 hour after lumbar puncture in all patients. Papilledema is an infrequently observed sign in infants and young children with ABM. In patients with clinical evidence of raised ICP, a CT scan should be done to exclude a mass lesion and empiric treatment of meningitis started. Clinical signs of raised ICP are a more reliable indicator to withhold a lumbar puncture since even a normal CT scan does not exclude the imminent risk of coning.

Should Imaging be done in All Cases?

Sonography should be done in all neonates and infants less than 2 months since the risk of complications are higher. Contrast enhanced CT is the preferred modality if subdural empyema or parenchymal damage is suspected. CT is not required in uncomplicated meningitis.²⁰ These investigations should be considered in patients with:

- Sign of raised ICP
- Focal neurologic deficits
- Persistent fever
- Recurrent/focal seizures
- Prolonged coma
- Increasing head circumference.

What Laboratory Testing may be Helpful in Distinguishing Acute Bacterial from Other Neuroinfections?

Several other diseases particularly aseptic meningitis, tuberculous meningitis, cerebral malaria, brain abscess and lead encephalopathy present with signs and symptoms similar to ABM. A careful examination of CSF, which shows pleocytosis with polymorphonuclear predominance with reduced CSF sugar is highly suggestive of ABM. Gram stain and culture confirm the diagnosis. Partial treatment of meningitis with oral and systemic antibiotics often poses a diagnostic problem since CSF is rapidly sterilized though cell count, and CSF biochemical abnormalities persist. A combination of test results, however, may permit an accurate prediction of the likelihood of bacterial versus viral meningitis. Low CSF glucose concentration, high CSF protein concentration, a CSF leukocyte count of >1000 leukocytes/mm³ are individual predictors of bacterial, rather than viral meningitis.

TREATMENT ISSUES

Treatment can be broadly categorized into:

- Antibiotic therapy
- Supportive care
- Adjuvant therapy.

Antibiotic Therapy

What should the Initial Empiric Therapy for a Suspected Case of Meningitis?

The initial antibiotic regimen should be such that covers all the likely pathogens anticipated according to the age of the child, combination should not be antagonistic and it should achieve bactericidal concentrations in the CSF. Later the treatment can be modified depending upon the result of Gram stain and CSF culture. Various antibiotics used in initial therapy and subsequent treatment are shown in Table 1.

A combination of vancomycin and ceftriaxone is recommended as initial empiric therapy in USA.²¹ This is based on the fact that HIB is no longer a common organism in USA and the likelihood of *Pneumococcus* being etiologic agent has increased. Besides there is high rate isolation of PRSP in USA. Reports of increase in frequency of PRSP are emerging throughout the world.²² In areas, which have included pneumococcal vaccination the epidemiology may change yet further. The scenario in India is altogether different. Hib continues to be a major organism and PRSP is not a significant problem. There is no justification of giving vancomycin as initial empiric therapy in this context. A recent study conducted on children aged 5 to 10 years resistance in Sp was low (3.3 percent) but 22.9 percent of *H. influenzae* isolates were ampicillin-resistant.²³ Hence, the initial antibiotic recommended in our country continues to be third generation cephalosporin (cefotaxime or ceftriaxone). For patients with cerebrospinal fluid shunts, broad spectrum antibiotics against gram-positive and gram-negative organisms should be given, such as a combination of vancomycin and ceftazidime. In a recent trial patients given slower Intravenous infusion of cefotaxime along with oral paracetamol had lower mortality during the first 72 hours as compared to recipients of conventional bolus doses.^{23a} Further trials of this simple approach are warranted.

Role of Newer Antimicrobials

Fourth-generation cephalosporins: A fourth-generation cephalosporin, cefepime, has been shown to be safe and therapeutically equivalent to cefotaxime in the treatment of bacterial meningitis in infants and children.²⁴ Cefepime also has greater *in vitro* activity than the third-generation

Table 1: Antibiotic therapy in cases of bacterial meningitis

Initial empiric therapy			
	Age	Drug of choice*	
	0–2 months	Ampicillin + Cefotaxime	
	2 months to 12 years	Ceftriaxone or Cefotaxime	
Subsequent antibiotic therapy			
Pathogen	Drug of choice	Alternative choice	Duration of therapy (days)
Pathogen unknown	Ceftriaxone or cefotaxime	Cefipime	14
<i>H. influenzae</i>	Ceftriaxone	Cefipime	10
Type b <i>S. pneumoniae</i>	or cefotaxime		
• Penicillin-sensitive	Crystalline penicillin	Chloramphenicol	14
• Penicillin-resistant	Ceftriaxone + Vancomycin	Newer quinolone/ Meropenem	14
<i>N. meningitidis</i>	Crystalline penicillin	Ceftriaxone/Chloramphenicol	7–10
Staphylococci	Nafcillin	Vancomycin	2–3 weeks
<i>Pseudomonas</i>	Ceftazidime + Amikacin	Meropenem	3 weeks
<i>Listeria monocytogenes</i>	Ampicillin/Penicillin	Trimethoprim+ Sulfamethoxazole	21 days
Group B Streptococcus	Ampicillin/	Cefotaxime	14–21 days
<i>E. coli</i>	Cefotaxime + gentamicin	Meropenem/Aztreonam/Fluoroqui- nolones	21 days #

* Dosage Schedule (All drugs to be given intravenously)

Duration in the neonate is 2 weeks beyond the first sterile CSF culture or 3 weeks, whichever is longer.

cephalosporins against *Enterobacter* species and *Pseudomonas aeruginosa* and has been used successfully in some patients with meningitis caused by these bacteria making it a useful agent in the treatment of patients with bacterial meningitis.

Meropenem: Meropenem, which has a broad range of *in vitro* activity, has been studied in both children and adults with bacterial meningitis. In these studies, meropenem has been shown to have clinical and microbiologic outcomes similar to those of cefotaxime or ceftriaxone and can be recommended as an alternative to these agents for treatment of bacterial meningitis.²⁵ Meropenem is especially useful in patients with meningitis caused by gram-negative bacilli that produce extended-spectrum β -lactamases or those that may hyperproduce β -lactamases (i.e. *Enterobacter* species, *Citrobacter* species, or *Serratia marcescens*). However, meropenem may not be a useful alternative agent for treatment of pneumococcal isolates that are highly-resistant to penicillin and cephalosporins.

Fluoroquinolones: The fluoroquinolones have been used successfully in some patients with meningitis due to gram-negative organisms. The newer fluoroquinolones (e.g. gatifloxacin, and moxifloxacin) have enhanced *in vitro* activity against *S. pneumoniae* and have been studied in experimental animal models of pneumococcal meningitis. Trovafloxacin was compared with ceftriaxone, with or without vancomycin, in a multicenter, randomized trial in children with bacterial meningitis. The overall efficacy in both treatment groups was comparable in terms of CSF sterilization and clinical success at the end of treatment.²⁶ Although trovafloxacin was since been withdrawn because of concerns of liver toxicity, this study suggests the potential usefulness of the new fluoroquinolones in therapy of ABM. Because there is insufficient evidence of their clinical efficacy till now and these agents have not been studied in newborns and children, these should only be considered in patients who are not responding to currently recommended therapy.^{27,28}

Subsequent therapy depends on the organism isolated and its antibiotic sensitivity. Cefotaxime or ceftriaxone is adequate if pneumococci are susceptible to cefotaxime. However, if *S. pneumoniae* isolates have higher MIC for cefotaxime and fall in the intermediate resistance group, there have been concerns regarding prompt sterilization of the CSF, and a high-dose of cefotaxime (300 mg/kg/d) with vancomycin 60 mg/kg/d may be preferred. In the rare event that pneumococcal isolate has high resistance to cefotaxime or ceftriaxone, vancomycin alone may not be adequate for prompt sterilization of the CSF and rifampin should be added to the regimen or else alternative regimens such as cefepime be given.

For multiple drug resistant staphylococci, vancomycin remains the drug of choice. Combination beta lactam-beta lactamase inhibitor antibiotics (e.g. tazobactam, sulbactam) should not be used to treat meningitis because data are insufficient regarding their penetration of the CNS.

Duration of Therapy

The duration of antimicrobial therapy is based on the causative agent and clinical response (Table 2).^{6,29} The duration of treatment is 7 to 10 days for meningitis due to HIB, 10 to 14 days for Sp. Short courses of treatment are effective for meningococcal meningitis. In a recent RCT, treatment with ceftriaxone given for 5 days was as efficacious as 10 days in meningitis caused by HIB, Sp and Nm.

Since the study included children who had sterile CSF at 48 hours of treatment with ceftriaxone the results cannot be generalized.^{29a}

Longer duration of treatment is required in meningitis due to bacteria such as nontyphoidal *Salmonella*, *E. coli* and *Pseudomonas*. Complications such as subdural empyema, prolonged fever, persistence of meningeal signs or development of nosocomial infections need longer treatment. In such cases, discontinuation of antimicrobial therapy is individualized.

Supportive Therapy

Monitoring

The first 3 to 4 days of treatment are critical because life-threatening complications of meningitis occur most frequently during this period. It is advisable to manage infants and children with meningitis in hospital that has staff with expertise in caring for infants and children who are critically-ill. Vital signs of patients should be monitored regularly during the first 24 to 28 hours of treatment. The patient should be kept nil orally to prevent aspiration. Neurological examination should be performed initially and daily throughout hospitalization. Blood urea, blood sugar, blood gases, serum electrolytes, blood and urine osmolality, urine output, body weight should be monitored closely.

Table 2: Recommended dosages of antimicrobial therapy in patients with bacterial meningitis (A-III)

		Total daily dose (dosing interval in hours)	
		Neonate (Age in days)	Infants and children
Antimicrobial agent	0-7	8-28	
Amikacin	15-20 mg/kg (12)	30 mg/kg (8)	20-30 mg/kg (8)
Ampicillin	150 mg/kg (8)	200 mg/kg (6-8)	300 mg/kg (6)
Cefepime	150 mg/kg (8)
Cefotaxime	100-150 mg/kg (8-12)	150-200 mg/kg (6-8)	225-300 mg/kg (6-8)
Ceftazidime	100-150 mg/kg (8-12)	150 mg/kg (8)	150 mg/kg (8)
Ceftriaxone	100 mg/kg (12-24)
Chloramphenicol	25 mg/kg (24)	50 mg/kg (12-24)	75-100 mg/kg (6)
Gentamicin	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)
Meropenem	120 mg/kg (8)
Nafcillin	75 mg/kg (8-12)	100-150 mg/kg (6-8)	200 mg/kg (6)
Oxacillin	75 mg/kg (8-12)	150-200 mg/kg (6-8)	200 mg/kg (6)
Penicillin G	0.15 mU/kg (8-12)	0.2 mU/kg (6-8)	0.3 mU/kg (4-6)
Rifampin*	...	10-20 mg/kg (12)	10-20 mg/kg (12-24)*
TMP-SMZ	10-20 mg/kg (6-12)
Vancomycin	20-30 mg/kg (8-12)	30-45 mg/kg (6-8)	60 mg/kg (6)

Note: TMP-SMZ, trimethoprim-sulfamethoxazole. Dosage based on trimethoprim component

*Maximum daily dose of 600 mg.

Should Fluids be Restricted Routinely in All Cases of ABM?

Maintenance of systemic blood pressure is critical to maintain cerebral blood flow. Concurrence of shock and cerebral edema is a therapeutic challenge. The treatment of shock with fluids and inotropes takes priority in such cases. It is common practice to restrict fluids to two-third maintenance to prevent SIADH. Children with meningitis have excess total and extracellular water an appropriate secretion of ADH and mild hypertension, which is required to overcome raised ICT and maintain cerebral blood flow and perfusion. Hence, fluid restriction may increase the likelihood of adverse outcome.³⁰ A recent meta-analysis concluded that there is some evidence to support the use of intravenous maintenance fluids in preference to restricted fluid intake in the first 48 hours in settings where patients present late.³¹ However, fluid therapy should be dictated by clinical condition and care should be taken to avoid over hydration. Hyponatremia is a frequent finding in patients with meningitis and can be due to SIADH or volume contraction. Therefore, the cause of hyponatremia should be assessed along with clinical signs of volume depletion and biochemical parameters, i.e. serum and urine osmolality. The child should receive fluids sufficient to maintain systolic blood pressure at around 80 mm Hg, urinary output of 500 ml/m²/d, and adequate tissue perfusion.

To maximize venous drainage and reduce intracranial pressure elevate the head end of the bed by 30°. Osmotic diuretics such as Mannitol (0.5-1 g/kg) and oral glycerol can be used to reduce ICP. Glycerol was found to prevent severe neurological sequel in one large randomized controlled trial.^(31a) Because of its safety, wide availability, low cost, and oral administration, it should be particularly useful in resource-limited settings. Hyperventilation to maintain the arterial pCO₂ between 27 and 30 mm of Hg may also be used to reduce ICP. Aggressive hyperventilation may be counterproductive as it causes reduction of already compromised CBF with resultant ischemic damage.

Seizures are common during the course of bacterial meningitis. Metabolic complications like hyponatremia, hypocalcemia and hypoglycemia must be excluded and specific therapy instituted if present. Immediate management of seizures includes intravenous diazepam (0.1-0.2 mg/kg/dose) or lorazepam (0.05 mg/kg/dose). This is followed by a loading dose of phenytoin (15 mg/kg) and the maintenance dose of 5 mg/ kg/ 24 h for further control of seizures. Phenytoin is preferred over phenobarbitone because it causes less CNS depression and allows assessment of sensorium. Anticonvulsants can be discontinued after a few days unless there is evidence of persistent seizure activity.

Adjunct Therapy

Adjunctive anti-inflammatory agents, which may be of benefit in treatment of bacterial meningitis include

corticosteroids and newer anti-inflammatory drugs which are still in experimental stage.³²

Use of corticosteroids-steroids have anti-inflammatory effects and decrease the release of various cytokines. They inhibit the transcriptions of mRNA for TNF- α and IL-1, and the production of prostaglandins and PAF, reduce vasogenic cerebral edema, and reduce the production of inducible nitric oxide synthetase. The maximum benefit of dexamethasone is obtained when it is given along with the first dose of antibiotics. A dose of 0.4 mg/kg given every 12 hours for a total duration of two days proved to be safe and as efficacious as the dose of 0.15 mg/ kg given every six hours for four days.³³ The benefit of dexamethasone use in these studies was only moderate and limited to decrease in frequency of audiologic sequel in meningitis due to HIB.^{34,35} Similarly, better outcome was reported with use of dexamethasone in pneumococcal meningitis in children.³⁶ A recent cochrane review; concluded that use of corticosteroids in children reduced the incidence of deafness in meningitis caused by all common bacteria.³⁷ The experience from developing countries is, however, different. A recent large double blind placebo-controlled trial from Malawi showed no benefit of dexamethasone as an adjuvant treatment in children with acute bacterial meningitis.³⁸ In resource, poor countries where the patients are often malnourished and brought late to the health facility after receiving oral medications, one should use steroids with caution. There is only one published trial that has evaluated the efficacy of adjunctive dexamethasone in neonates with bacterial meningitis.³⁹ This trial was small and underpowered but did not find significant difference in outcome in 2 groups. There is insufficient data to support use of dexamethasone in treatment of neonatal meningitis. Dexamethasone should not be used if aseptic or nonbacterial meningitis is suspected and if it is started before the diagnosis is established it should be discontinued immediately. Dexamethasone should not be used in partially-treated meningitis.

Newer Drugs

Anti-endotoxin antibodies have been produced by monoclonal antibody technology and appear to have beneficial role in ABM caused by gram-negative organisms. Monoclonal antibodies against TNF, IL-1B and against CD 18 cells may help in reducing inflammation as shown in experimental studies. Other drugs tried in experimental studies include nonsteroidal anti-inflammatory agent, and pentoxifylline.⁴⁰

Prognosis

The prognosis of a patient with pyogenic meningitis depends on many factors including age, causative microorganism, bacterial density, intensity of host's inflammatory response and time taken to sterilize the CSF. Case fatality is reported to be 3 to 6 percent in developed countries but

higher mortality (16 percent) is reported from developing countries.¹ Most deaths occur within first 48 to 72 hours. Early fatality is most often due to septic shock. Close monitoring for signs of septic shock and brain herniation should be done in first 2 to 3 days of hospitalization.

Neurodevelopmental sequel are seen in 10 to 20 percent of patients.^{2,9} Baraff et al in a meta-analysis of 19 reports estimated that 83.6 percent patients had no sequel.² The common sequel reported were deafness (10.5%), mental retardation (4.2%), epilepsy (4.2%) and motor deficits (3.5%). The sequel of bacterial meningitis may improve with time and even resolve completely. The potential for recovery is attributed to the plasticity of brain. Focal neurological signs at admission have been found to be reliable predictors of permanent sequel especially later epilepsy. Persistence of fever, neck rigidity and reluctance to leave the supine position beyond the first week was associated with risk of neurologic complication or sequel.⁴¹ Prognosis is the poorest among infants less than 6 months, in those with delayed sterilization of the CSF, seizures beyond 4th day of hospital stay, coma, (Glassgow coma scale <8), focal neurological signs on presentation, infection with Sp, and other organisms like Salmonella or Pseudomonas infection. All infants recovering from meningitis should be screened.

PREVENTION

Prevention of ABM is possible with:

- Prevention of secondary cases with antibiotic chemoprophylaxis of index case and close contacts
- Vaccination of susceptible population with specific vaccines.

Vaccination is not a substitute for chemoprophylaxis because secondary cases develop within 2 to 7 days of presentation of index case and vaccination is not effective at that stage.

Primary Prevention

Immunization with *H. influenzae* type b vaccines-HIB OC (3 doses I/M at 2, 4, 6 months and a booster at 15 months) or PRP-OMP (2 doses I/M at 2, 4 months and booster at 12 months) are routinely given in most developed countries with impressive decline in meningitis due to HIB.⁴² Vaccine is efficacious and its cost effectiveness should be evaluated in developing countries.

Impressive results with use of pneumococcal 7 valent conjugate vaccine, (PCV7) which contains common prevalent serotypes have been reported till 2008.⁴³ Subsequently, PCV 7 was incorporated in immunization schedule of USA. Now, Since 2009 13 valent pneumococcal vaccine is available, it has additional strains 1,5,7F,3,6A,19A. Three doses of PCV 13 are recommended to be given at 2, 4 and 6 months of age and a fourth dose at 12 to 15 months. PCV 10 has been launched in India in 2011. It has 1,5 and

7F in addition to the PCV 7 strains. Both PCV 13, PCV 10 can be used for prevention of pneumococcal disease. High-risk group > 5 years should get 23 valent polysaccharide pneumococcal vaccine.^{43a}

Quadrivalent meningococcal vaccine Meningococcus A, C, Y, or W135 is available and given in selected groups, e.g. pilgrims going for haj; adolescents in dormitories and soldiers. Mass vaccination is recommended in areas with high incidence, e.g. in sub-Saharan Africa and during epidemics. Immunization against meningococcal serogroup C was introduced in the UK in 1999 and a marked reduction in the incidence of meningococcal infection has been observed since then.⁴⁴ A trial of combined pneumococcal-meningococcal vaccine demonstrated reduced immunogenicity to meningococcal group C as well as to concomitantly administered Hib vaccines.⁴⁵ The advent of new conjugated vaccines that include a larger number of *S. pneumoniae* serotypes will add broader coverage against Sp. worldwide. Effective conjugate vaccines against non-group B meningococci are already available and promising group B meningococcal vaccine candidates are currently undergoing phase III clinical trials. Further improvements in vaccine development may provide a single effective and cheap vaccine for common pathogens of ABM and reduce the global burden of ABM in coming years.

Recommendations for Prevention of Secondary Cases among Close Contacts⁴²

H. Influenzae Type b Infection

All household contacts should be given rifampicin 20 mg/kg/day (max 600 mg/day) for four days if there is child <5 years at home.

Pneumococcal Meningitis

Chemoprophylaxis not normally indicated for close contacts.

Meningococcal Infection (Should be given one of the Following)

- Rifampicin 600 mg every 12 hours for two days for adults; for children the dose is 10 mg/kg (under 1 year, 5 mg/kg) every 12 hours for two days orally.
- Ceftriaxone 250 mg in adults (child <12 years, 125 mg) intramuscularly as a single dose.
- Ciprofloxacin 500 mg orally as a single dose in adults

Emergence of antimicrobial resistant bacteria are posing a constant challenge in treatment of acute bacterial meningitis. Besides there is a need for effective strategies to prevent neuromorbidity which is hampered by incomplete understanding of pathogenesis of neurological sequelae. Most meningitis causing bacteria cross the blood brain barrier involving specific interaction between the pathogen and host receptors. Blockade of these host

receptors can prevent the microbial invasion of CSF.⁴⁶ This host based novel approach may help in prevention and treatment of bacterial meningitis.

Cerebral Palsy: Diagnosis, Risk Factors, Early Intervention and Management of the Spastic Child

Maurice G Sholas

INTRODUCTION

The objectives of this chapter target primary care pediatricians. They include:

- A review of the epidemiology of cerebral palsy
- A review of categorization and definitions relevant to cerebral palsy
- A review of the differential diagnosis of and concepts central to the early identification of cerebral palsy
- A review of treatment options for cerebral palsy and common comorbidities
- A review of spasticity management.

The pediatrician, a family practitioner, or a physician extender is often the first point of contact with medical care for children. These primary care providers are essential members of the team that will ultimately be assembled to care for a child with cerebral palsy. Primary providers may not be required to diagnose and execute treatment in isolation from specialists. However, it is essential that primary care providers be familiar with the factors that predispose a patient to be at risk for and the early warning signs of cerebral palsy. This will lead to early diagnosis of affected individuals, early entry into specialized services, and effective education of the patient's parents. Many professionals argue for the diagnosis of cerebral palsy being made within the first year of life (Morgan et al 1996).

The care options available to a patient with cerebral palsy are heavily influenced by access to interventions that are recognized as the standard of care. Data shows that children with cerebral palsy from poor families, in rural settings, with illiterate parents had higher mortality than their counterparts in other social settings (Khan et al 1998). It is quite possible that these data from the developing world are also applicable in developed nations as some patients, by virtue of their psychosocial milieu, have less access to the standard of care. In addition to psychosocial barriers, geographic barriers can also influence

access. Thus, each practitioner must find how to deliver the best care that utilizes the best evidence available while respecting the realities that limit each medical professional, family and community.

Epidemiology and Definitions

Cerebral palsy is a diagnosis, which is used for a constellation of findings that are the result of multiple etiologies. Children with this diagnosis have abnormal muscle tone, strength, and control. In addition, they have persistent primitive reflexes and abnormal postural reactions. These symptoms are due to a non-progressive lesion of the developing brain. Cerebral palsy is the most common physical disability of childhood (Kuban and Leviton 1994, Rosenbaum 2003). Nomenclature and standardization issues make it difficult to accurately assess worldwide prevalence. However, it is estimated to be 2 to 3 per 1000 and neither increasing or decreasing (Clark and Hankins 2003). Clark and Hankins compiled data for multiple countries in 2003 (Table 1). It is impressive that the rates in some developing nations are equivalent to those in developed nations. These data imply that cerebral palsy is a developmental event that in large part cannot be prevented (Clark and Hankins 2003).

Since diagnosis with cerebral palsy does not convey the primary type of tone abnormality or distribution, it is important to sub-classify the type of cerebral palsy and topographical distribution of the symptoms (Fig. 1). With respect to sub-type, the vast majority of cerebral palsy patients are spastic (Koman et al 2004), but there are others with a hypotonic variant, dystonic (athetoid) variant, or a mixed-clinical picture. For topography, the number and location of affected extremities is used. If one limb is affected, the patient has monoplegia. When primarily both lower extremities are affected the patient has diplegia. Triplegia implies that there are three extremities

Table 1: Cerebral palsy rates by country from 1985 to 1990

Country	Prevalence per 1000
Australia	1.6
Canada	2.6
Denmark	2.4 to 3.0
England	2.3
India	1.2
Ireland	2.2
Scotland	2.1
Slovenia	2.3
Sweden	2.4

**Fig. 1:** Topographical distribution of cerebral palsy

affected. Quadriplegia denotes that all four extremities are involved. And, hemiplegia means that one side of the body, an arm and a leg, is involved and the other is intact. For example, a patient that has cerebral palsy with spasticity affecting their right arm and leg is called a spastic hemiplegic patient.

Diagnosis with cerebral palsy also does not imply functional severity or prognosis. Thus, there are scales for categorization that convey more information about the cerebral palsy patient. The gross motor function classification (GMFC) system was created (Palisano et al 1997) in the late 1990's. Eventually this system proved reliable over time and stable as the child grew and developed (Wood and Rosenbaum 2000). In this system (Table 2), children are classified from level I (mild) to level V (severe). The

functional domains are separated into goals for children before their second birthday, between 2 and 4 years old, between 4 and 6 years old, and between 6 and 12 years old. The tasks used for classification are heavily weighted toward physical ones, thus children with profound physical disability will be classified as more severe even if their cognitive function is within normal limits. Using this system, a 6-year-old patient with cerebral palsy that has spasticity affecting his lower extremities to the degree that he requires an assistive device to walk is labeled a spastic diplegic cerebral palsy patient with a GMFC III. Additional functional classification systems include the physician rating scale (gait analysis), gross motor performance index, pediatric evaluation of disability index, and the functional independence measure in children (Koman et al 2004).

Nearly, 70 percent of events that lead to cerebral palsy are *in utero* (Rosen and Dickenson 1992). The largest contributing risk factors to cerebral palsy are unexplained. Of those identified, some are prenatal, others are neonatal and those remaining are postnatal (Table 3). Prenatal risk factors include (Koman et al 2004, Holm 1982, Nelson and Grether 1999, Baawi et al 1998, Matthews and Wilson 1999): congenital malformation, maternal uterine infection, reproductive inefficiency, toxic/teratogenic agents, maternal retardation, maternal seizures, maternal hyperthyroidism, placental complications, multiple births, and abdominal trauma. Neonatal risk factors include (Koman et al 2004, Holm 1982, Nelson and Grether 1999, Badawi et al 1998, Matthews and Wilson 1999): prematurity, low birth-weight, abnormal presentation for delivery, intracranial hemorrhage, hyperbilirubinemia, infection, bradycardia, hypoxia, and seizures. Postnatal risk factors include (Koman et al 2004, Holm 1982, Nelson and Grether 1999, Badawi et al 1998, Matthews and Wilson 1999): trauma, encephalitis, intracranial hemorrhage, and coagulopathies. Overall, congenital infections account for 5 to 10 percent of cases (Paneth 1986). Undetected congenital brain anomalies are responsible for an additional 5 to 10 percent of cases (Paneth 1986). Genetic abnormalities are involved in 2 to 5 percent of cases (Paneth 1986). Cerebral palsy risk factors are often subdivided into those that affect term infants and those associated with prematurity. In term infants, perinatal asphyxia is present in only 25 to 30 percent of cases (Paneth 1986). Overall, infants that are at greatest risk are premies with intrauterine growth retardation delivered between 34 and 37 weeks (Blair and Stanley 1990).

Screening and Diagnosis

All children do not necessarily need to be screened for cerebral palsy. But, in patients that are at risk, a full differential diagnosis must be considered and the collection of medical data are important. Children most at risk are (Morgan et al 1996): less than 1,500 grams, required

Table 2: Gross motor function classification

	<i>Before 2nd Birthday</i>	<i>Between 2nd and 4th Birthday</i>	<i>Between 4th and 6th Birthday</i>	<i>Between 6th and 12th Birthday</i>
Level I	Move in/out of sitting both hands free Crawl on hands and knees Walk 18-24 months w/o assistive device	Sit hands free Move in/out of floor sitting and standing without help Walk w/o assistive device as preference	In/Out chair w/o hand support Transition to stand without using objects for support Walk in/out doors, climb stairs	Walk in/out doors Run and jump but speed and balance are reduced
Level II	Sit using hands for support Creep on stomach or crawl on hands and knees Pull to stand and cruise	Sit but difficult when both hands free Move in/out of sit w/o assist Crawl "w" reciprocal pattern Cruise or walk with assist device	Sit in chair with both hands free Move to stand from chair but will use object to "push off" Walk without assistive device Climb stairs holding rail No run/jump	Walk in/out doors Climb stairs holding rail Some challenge with uneven terrain Minimal run and jump ability
Level III	Sit with low back support Roll and creep forward on stomach	Floor sit via "w" sitting May need assist to assume sit Creep or crawl w/o reciprocal movement Walk short distances with device or assist	Sit regular chair with trunk or pelvis support Move in/out of sit using stable surface to push/pull Walk with assist device Transported for long distances	Walk indoors on level surface "w" assist device May climb stairs holding rail Propel chair manually or transport for distances or rough terrain
Level IV	Prone head control good Support required for floor sitting Roll to supine, may roll prone	Floor sit when placed but must use hands for support Adaptive equipment for sit and stand Roll creep or commando crawl	Sit with adaptive seating for trunk control Move in/out chair with assistance Walk with device but tough to turn or do uneven surfaces Transported in community Self-mobile "w" power chair	Maintain goals from 6 years old Use chair mobility for school and community Self mobility with power chair
Level V	Poor voluntary control of movement Unable to maintain antigravity head and trunk postures Assistance to roll needed	All areas of motor function limited No means of independent mobility Some self-mobile with power chair	All areas of motor function limited No means of independent mobility Power chair possible with extensive adaptations	All areas of motor function limited No means of independent mobility Power chair possible with extensive adaptations

Table 3: Risk factors for cerebral palsy

<i>Prenatal risk factors</i>	<i>Neonatal risk factors</i>	<i>Postnatal factors</i>
<ul style="list-style-type: none"> • Congenital malformation • Maternal uterine infection • Reproductive inefficiency • Toxic/teratogenic agents • Maternal retardation • Maternal seizures • Maternal hyperthyroid • Placental complications • Multiple births • Abdominal trauma 	<ul style="list-style-type: none"> • Prematurity (< 32 weeks) • Low birth-weight (< 1500 grams) • Growth retardation • Abnormal presentation • Intracranial hemorrhage • Hyperbilirubipenia • Infection • Bradycardia with hypoxia • Seizures 	<ul style="list-style-type: none"> • Trauma • Infection (encephalitis) • Intracranial hemorrhage • Coagulopathies

assistive ventilation more than 48 hours, had five minute APGAR scores below 4, or infants with any neurological complication. Thus cerebral palsy must be considered in infants that present early in life with seizures, meningitis, hydrocephalus, intraventricular hemorrhage, or hypotonia (Morgan et al 1996).

A complete differential diagnosis for cerebral palsy is lengthy. Since it is an “umbrella term” encompassing a spectrum of findings, other more specific diagnoses must be ruled out. Badawi and colleagues were comprehensive in their description of the differential diagnosis in 1998. Genetic syndromes like hereditary spastic diplegia, trisomy 13 and trisomy 18 can lead to abnormal tone and mimic cerebral palsy. Similarly, metabolic disorders, such as mitochondrial pathology, and syndromes with vascular defects, such as Moyamoya disease, can cause insults to the immature brain that cause muscle tone abnormalities. Finally, neural tube defects, neuromuscular disorders and motor problems caused by tumors are also in the differential. If there are co-morbidities or findings consistent with an item on the differential diagnosis, that work-up should take precedence. None of the aforementioned entities are included in the spectrum of cerebral palsy.

The physical exam at the 4, 6, 9 and 12-month time points are critical to establishing or augmenting a clinical suspicion for cerebral palsy. Some investigators have devised a formal battery of test items to screen for abnormal motor patterns (Morgan and Aldag 1996). The early motor pattern profile uses a 3-point scale for rating each of 15 items (Table 4). Zero is given if the finding is absent, 1 if it is present intermittently, and 2 if it is severe. Any child at 6 months that scores greater than 7 is very likely to have cerebral palsy. The major drawback of this method is sensitivity, as many children with mild cerebral palsy do not score high enough to be screened in by the scale but later meet criteria for diagnosis. Allen and Alexander in 1997 found that no one test at any isolated point in time was as predictive as serial screening using 6 motor milestones:

- Roll prone to supine
- Roll supine to prone

- Sit with support
- Sit without support
- Crawl
- Cruise.

If there is a delay in any one of these milestones, the patient should be followed closely. A delay of more than three is very indicative that the patient may have cerebral palsy and needs a referral for a comprehensive developmental assessment. In addition to charting motor milestones, exam findings like a persistent dominant asymmetric tonic neck reflex (ATNR), trunk hypotonia with hypertonic extremities, asymmetric limb usage, and a paucity of typical movements are also predictive of major motor dysfunction (Lacey and Henderson Smart 1998, Aneja 2004). The need for missed or late motor milestones and persistence of primitive reflexes make it very difficult to come to cerebral palsy as a definitive diagnosis prior to 4 to 6 months of age (Davis 1997, Aneja 2004).

Imaging studies can be useful and predictive in the neonatal setting. Many use them as an adjunct to the physical findings and patient history. They have been used for term and premature infants. These findings may be the earliest clues that a child falls into a high-risk category to develop cerebral palsy (Palmer 2004). Cranial ultrasound and magnetic resonance imaging (MRI) are the most commonly used neuroimaging studies (Accardo et al 2004). The type of neurological lesion seen is suggestive of the future subcategory of cerebral palsy (Palmer 2004, Okumira, Hyakawa et al 1997, Okumira, Kato, et al 1997). Mild periventricular leukomalacia by ultrasound or MRI is associated with later development of spastic diplegia. Severe periventricular leukomalacia or global hypoxic ischemic encephalopathy is associated with spastic quadriplegia. Spastic hemiplegia is associated with prenatal strokes and intraventricular hemorrhage. Hypoxic ischemic encephalopathy affecting deep brain structures is associated with dystonia. Initial use of imaging studies were focused on the neonatal population in the intensive care unit, but many primary care physicians and specialists have begun using imaging studies to look for findings that corroborate clinical suspicion and/or historical data.

Table 4: Early motor pattern profile

Item	Description	Score
<i>Head Lag</i>	Pull to sitting from supine and assess alignment of head with trunk	0 – never present 1 – inconsistent or partial 2 – severe
<i>Slip through</i>	Support in vertical suspension with hands in axillae and assess need for lateral pressure to prevent child from slipping through	0 – never present 1 – inconsistent or partial 2 – severe
<i>Astasis</i>	Place in supported standing and assess weight bearing	0 – never present 1 – inconsistent or partial 2 – severe
<i>Hip abduction</i>	With legs flexed at the knees abduct hips and assess resistance	0 – never present 1 – inconsistent or partial 2 – severe
<i>Ankle dorsiflexion</i>	With leg extended dorsiflex foot at the ankle and assess resistance	0 – never present 1 – inconsistent or partial 2 – severe
<i>Reflexes at ankle</i>	Assess response at ankles	0 – never present 1 – inconsistently present or partial 2 – severe
<i>Asymmetric tonic neck reflex (ATNR)</i>	Rotate head to one side in supine and observe the position of the extremities	0 – never present 1 – inconsistent or partial 2 – severe
<i>Tonic labyrinthine reflex</i>	Place hands under shoulders in supine and lift slightly, then observe efforts to flex forward	0 – never present 1 – inconsistent or partial 2 – severe
<i>Equilibrium in sitting</i>	Sit in lap and shift from side to side and observe efforts to maintain neutral positioning.	0 – never present 1 – inconsistent or partial 2 – severe
<i>Protective extension</i>	Push to one side in sitting and observe efforts to stop falling with lateral propping	0 – never present 1 – inconsistent or partial 2 – severe
<i>Fisting</i>	Hands remain tightly clenched at rest	0 – never present 1 – inconsistent or partial 2 – severe
<i>Shoulder retraction</i>	Arms flexed and shoulders retracted posteriorly in sitting	0 – never present 1 – inconsistent or partial 2 – severe
<i>Tonic extension</i>	Backward thrusting in sitting or when lifted from supine	0 – never present 1 – inconsistent or partial 2 – severe
<i>Scissoring</i>	Legs adduct in a scissoring motion in vertical suspension or standing	0 – never present 1 – inconsistent or partial 2 – severe
<i>Equinus</i>	Up on toes in supported standing	0 – never present 1 – inconsistent or partial 2 – severe

Co-Morbidities and Symptomatology

A static lesion causes cerebral palsy, but the effects of this lesion are dynamic over the lifetime of the child. Multiple functions mediated by the central nervous system are disordered in association with cerebral palsy (Koman et al 2004, Matthews and Wilson 1999). Mental retardation is present in 30 to 40 percent of patients with cerebral palsy (Koman et al 2004, Liptak and Accardo 2004). If

patients that have mild learning disabilities are included, up to 75 percent of patients with cerebral palsy have disorders of higher cortical processing (Liptak and Accardo 2004). That percentage is high, but it is critical to note that diagnosis with cerebral palsy does not automatically imply mental retardation. Seizure disorders are present in 35 percent of these patients (Koman et al 2004, Liptak and Accardo 2004). Some older references placed this

number closer to 50 percent (Matthews and Wilson 1999). Both mental retardation and epilepsy have a higher incidence in profoundly impaired spastic quadriplegics than other types of CP. Hemiplegic children have less cognitive impairment, but a significant occurrence of behavioral problems like emotional disorders, conduct disorders, or situational hyperactivity (Liptak and Accardo 2004). With respect to complex motor task mediation, 25 percent of cerebral palsy patients cannot walk, while greater than 50 percent walk without assistance of the upper extremities (Koman et al 2004). Cognitive impairment, seizure activity and mobility impairment are present to varying degrees in cerebral palsy patients.

The musculoskeletal complications of cerebral palsy can be mild to severe. Scoliosis, hip dislocations, flexion contractures at the knees and hips, as well as equinovarus deformities of the feet must be considered (Staheli 2001). For patients that are non-ambulatory, routine screening of spine and pelvis is common practice. These patients seem to be more at risk than their more functional counterparts because abnormal tone contributes to neuromuscular scoliosis and weight bearing via standing is crucial to the normal development of the acetabulum and femoral neck. Upper extremity deformities like thumb-in-palm deformity, wrist flexion contracture and internal rotation at the shoulder also can convey morbidity in patients with cerebral palsy (Staheli 2001). In addition to causing pain and limiting care/comfort for the patients, musculoskeletal deformities can contribute to increased risk of pressure sores. Finally, patients that are non-ambulatory secondary to catastrophic disability are at significant risk for osteopenia (Henderson et al 2002, Tasdemir 2001). If the osteopenia is severe the patients have morbidity and possible mortality from pathological fractures. Treatment of disuse osteopenia is an area of active research, thus there are few evidence-based guidelines.

Gastrointestinal pathology and oro-motor dysfunction are associated with cerebral palsy. They are a large part of the reason these patient can be at risk for or relatively malnourished (Sleigh and Brockelhurst 2003, Rogers 2004, Matthews and Wilson 1999). One of the most common finding in clinical practice of cerebral palsy patients is constipation (Matthews and Wilson 1999). This is most likely related to some dysmotility or discoordination of the gut. Gastrointestinal reflux is also problematic in this population (Matthews and Wilson 1999). Both constipation and reflux may be independent or part of a larger oro-pharyngeal motor discoordination that impairs the ability of the patient to chew and swallow safely. Difficulty sucking, swallowing, chewing or controlling the tongue are associated with cerebral palsy as well as drooling (Matthews and Wilson 1999). Feeding or swallowing skills are powerfully prognostic of survival of children with CP (Rogers 2004). A large majority of cerebral palsy patients or their families report that feeding problems are present

(Rogers 2004), and this leads to the use of enteral feeding tubes in many (Rogers 2004, Sleigh and Brockhurst 2003). From drooling and dysphagia to constipation and reflux, gastrointestinal co-morbidities are common in this population. Ultimately, these findings contribute to the patient's nutritional status.

Pulmonary dysfunction is present in cerebral palsy patients (Matthews and Wilson 1999). These findings are secondary to reflux and aspiration of gastrointestinal contents. Plus there is an element of restrictive disease in cases of advanced scoliosis. Finally, infants born prematurely that ultimately develop cerebral palsy can have dysplastic lungs. Clinically, pulmonary findings can be mild to non-existent or quite serious. Severe cases lead to the need for tracheotomies and/or extreme caution when considering interventions that require surgical level anesthesia or conscious sedation.

Cerebral Palsy Treatment

Treating cerebral palsy is focused around treating the symptoms and sequel of the neurological insult. Considerable effort and resources have been used to find a "cure" to lesions of the central nervous system. None have been proven successful (Goldstein 2004). The quest to find cures parallels considerable efforts to find repairs for other processes that result in the death of terminally differentiated neural tissue. Some have postulated that since brain lesions in cerebral palsy have some relation to an ischemic insult, improving oxygen supply to the brain will improve neurological function and recovery. These inaccurate assertions are based on data from hyperbaric oxygen usage in acute traumatic brain injury (Rockswold et al 1992, Rockswold et al 2001). There is no evidence that delivering hyperbaric oxygen to patients with cerebral palsy will improve their neurological or functional status (Collet et al 2001, Hardy et al 2002). In fact, this intervention may cause harm, as it is associated with ear pain, myopia, convulsions, and pneumothorax (Essex 2003). The tank itself has also caused explosions and fires (Essex 2003). Other complementary or alternative treatments designed to improve the brain damage inherent in cerebral palsy include dietary supplements, herbal extracts, electrical brain stimulation, magnetic brain stimulation, acupuncture, craniosacral manipulation and spiritual energy channeling. "Reports of successful interventions [like these] are almost always anecdotal and lack the rigorous data that are collected in organized clinical trials." (Goldstein 2004).

Although the brain lesions themselves cannot be treated, physical interventions for patients with cerebral palsy are available through physical therapy, occupational therapy, speech/language therapy and various other therapeutic modalities. Early interventions to maintain range of motion and prevent progression of deformity are widely

practiced but do not have an irrefutable evidence basis (Turnbull 1993, Steultjens et al 2003). In spite of the data, therapeutic interventions serve an important role to assist with parent education, positioning, equipment acquisition, and functional optimization (Stempien and Gaebler-Spira 2000). Critics argue that patients who improve would do so with or without expensive, labor-intensive interventions. But, supporters counter that the benefits are plain and our experiments have not been designed well enough to capture these positive outcomes. Physical therapy (physiotherapy) focuses on mobility, range of motion, and positioning. Occupational therapy focuses on activities of daily living, self-care skills, sensory integration, and fine motor skills. Speech and language therapy seeks to improve the communication ability, cognitive capacity, and swallowing skills of patients. There is overlap of the disciplines through efforts to maintain normal positioning and reinforce functional skills for maximal independence. A new class of therapists is emerging. Functional therapists or therapy aids receive practical training in physical interventions without as heavy an emphasis on theoretical background. These professionals can be discipline-specific or a hybrid of physical therapy and occupational therapy without training in administration of modalities. The theoretical basis of many therapeutic interventions—including conductive education, neuro-developmental therapy (NDT) techniques, patterning, Adelphi Polish Suit Programs, and Vojta techniques – is varied, but no one philosophy has been shown to be superior to another (Stempien and Gaebler-Spira 2000, Goldsein 2004, Steultjens et al 2004, Turnbull 1993, Matthews and Wilson 1999, Koman et al 2004). In fact, many have very little objective evidence to support claims of efficacy (Stempien and Gaebler-Spira 2000, Goldsein 2004, Steultjens et al 2004, Turnbull 1993, Matthews and Wilson 1999, Koman et al 2004). Although evidence-based practice is difficult to establish for some physical interventions, there is solid evidence that muscle strengthening is efficacious for children with cerebral palsy (Koman et al 2004) as well as for the efficacy of functional (FES), not therapeutic (TES), electrical stimulation (Scheker et al 1999).

Therapists often fabricate splints and assist with durable medical equipment (Fig. 2) as part of their treatment program at the request of a physician. Splinting (orthotics) to increase the length of tendons limiting range of motion and to support weakened areas of the body (Koman et al 2004, Matthews and Wilson 1999, Stempien and Gaebler-Spira 2000) is a common approach in children with cerebral palsy that is non-invasive (Figs 3 and 4). Some splints are used passively as a conservative method of managing a flexible deformity. Others are used dynamically to improve function and mobility for identified tasks. Depending on the level of disability, complex seating systems, bathing chairs or communication devices are useful

Fig. 2: Young female with spastic quadriplegic cerebral plays, GMFC IV, in power wheelchair with her service dog (Photography credit: M Sholas, 2003) (For color version see plate 13)

for cerebral palsy patients (Stempien and Gaebler-Spira 2000, Matthews and Wilson 1999). Rehabilitation engineers are critical members of the team needed to treat functional limitations in these children. They work with the treating physician and therapists to fabricate and/or combine types of adaptive equipment. Cost and access to qualified professionals are common barriers to patients receiving appropriate equipment. In addition the environmental demands of some living environments can alter the effectiveness of splints, gait aids and seating systems used for patients with cerebral palsy.

Pharmacological and Surgical Agents of Spasticity Management

Pharmacological interventions that are the most evidence-based in children with cerebral palsy are those used to treat spasticity. Approaches to treat spasticity should have clear functional goals and involve the input of the patient/family and treating therapists. Spasticity can cause notable morbidity as it leads to contracture, exacerbates hip joint subluxation, increases caloric requirements, and contributes to pain/discomfort. Spasticity is commonly defined as velocity dependant tone. Table 5 lists large classes of

Table 5: Spasticity medications

	<i>Brand name</i>	<i>Generic name</i>	<i>Mechanism</i>	<i>Side effects facts</i>
	Lioresal® Dose 10-60 mg per day	Baclofen	CNS effect via GABA-B receptor	Nausea Sedation Lower seizure threshold 1st line
	Zanaflex® Dose not established in pediatric patients	Tizanidine	CNS effect via alpha 2 adrenergic receptor agonist	Nausea Sedation
	Valium® Dose 0.2-0.8 mg/kg/day	Diazepam	CNS effect via GABA-A receptor	Sedation Abuse potential Respiratory depression Easy to titrate small doses
	Dantrium® Dose 1-3 mg/kg	Dantrolene	Calcium channels in sarcoplasmic reticulum of muscle	Weakness in non-spastic muscle Interfere with voiding Elevated LFT's
	Catapress® Dose 5-30 mcg/kg/day	Clonidine	CNS effect via alpha 2 Adrenergic receptor	Hypotension Dry mouth Constipation PO and Transdermal preparations

pharmacologic interventions for spasticity. Oral medications, like baclofen, tizanidine and diazepam are excellent agents to treat global spasticity. Clonidine is also useful and it is delivered transdermally via a patch. Side effects for these agents include central nervous system depression and lowering of the seizure threshold. In spite of this, baclofen is commonly viewed as a first-line agent for spasticity management. Diazepam is useful in very young or small patients as it may be easily titrated to small doses. One final oral spasticity medication that is widely used is dantrolene. It does not affect the central nervous system. Instead, it works on the muscle fiber directly, but it can cause non-spastic muscles to be weak and impair bladder emptying. There are many types of spasticity medications.

Chemodenervation refers to regional spasticity management via interruption of the peripheral nerve and its communication with a spastic muscle (Koman et al 2004, Morton et al 2004, Pidcock 2004). Phenol (3-7% solution) and alcohol (45-100% solutions) nerve blocks cause a reduction in spasticity via chemically cutting the nerves that supply the spastic muscle. Given this mechanism, these agents are not used on mixed nerves or those that are primarily sensory. Good targets for phenol/alcohol nerve blocks are the obturator nerve and musculocutaneous nerve. Botulinum toxins are also a type of chemodenervation.

In, but they function via interruption of neural transmission by acetylcholine across the cleft from the nerve terminal to the muscle. Phenol/alcohol blocks require technical skill to perform, last for 4 to 8 months, and require general anesthesia to administer (Koman et al 2004). Botulinum toxins are costly, but they may be given to the unsedated patient in a clinic setting, and last 3 months (Pidcock 2004, Morton et al 2004).

The last major type of pharmacological treatment for spasticity involves using an intrathecal catheter to deliver baclofen directly to its site of action in the spinal cord. The intrathecal baclofen pump (ITB) is a technology that allows exquisite control of the administration of baclofen without systemic side effects (Albright 1996, Armstrong et al 1997, Coffey et al 1993). The doses used are 1/100th of the oral dose are adequate to control symptomatology. Aside from the significant cost of this technology, the pump implantation process and regular refills of the pump with medication, this intervention requires that the patient have regular access to a specialist trained in pump management. Plus, the patient must be near enough to emergency services that they could receive life-saving interventions if the pump or the catheter tubing malfunctions.

Surgical interventions are primarily neurosurgical or orthopedic surgery. In addition to implanting the ITB pump, selective dorsal rhizotomy (SDR) is an option to treat spasticity associated with cerebral palsy. SDR is a

permanent procedure that works to improve motor control by transecting a portion of the lumbar dorsal rootlets (Aiona and Sussman 2004, Koman et al 2004, Susman and Aiona 2004). This procedure is most often used on ambulatory spastic diplegic patients. It does not reverse or improve muscle weakness or treat dystonia so the patient population appropriate for treatment is specific (Koman 2004). Multiple tendon lengthening surgeries are performed to treat spasticity and its secondary consequences, contractures. Many of these surgical interventions are focused on preventing or ameliorating hip subluxation, excessive knee flexion, and equinovarus deformities of the foot. An important consideration when performing tendon lengthening is realizing that the treatment will weaken the treated muscle. Finally, scoliosis surgery is an important reality for many patients with cerebral palsy that have curves greater than 40 degrees and unresponsive to bracing (Koman et al 2004, Staheli 2001).

PSYCHOSOCIAL ASPECTS

In treating congenital physical disabilities, such as those associated with cerebral palsy, there are many issues unrelated to the disease process that strongly influence the outcome. The initial conversations with the parents are delicate and critical. Parents commonly have feelings of guilt, anxiety and anger (Wolraich 1986). These normal reactions must be acknowledged and managed to allow parent and child bonding. Anticipating the stress points of growth and development (Wolraich 1986)—diagnosis of the condition, start of schooling, reaching ultimate attainment, adolescence, and future placement—is important as any plan is constructed for treatment. Many parents hold out hope that the condition of their child will change, as there are children that are diagnosed early with cerebral palsy that subsequently “resolves” (Nelson and Ellenberg 1982). But, this subset appears to be composed of very mildly affected children. It is worthwhile to strongly encourage the parents to accept the permanence of diagnosis only when their beliefs compromise the ability of the child to receive treatment that is the standard of care. In the majority of children with cerebral palsy, aging into adulthood is an unexplored frontier. Improvements in care and technology have increased the numbers of adults with cerebral palsy. Many industrialized countries are planning and developing methods to cope with the changes that come with maturation. Sexuality, vocational opportunities, and independence are major challenges for the patient, the family and medical professionals (Matthews and Wilson 1999). For career planning, as reviewed by Matthews and Wilson, the following expectations are linked to these cognitive and physical deficits. Persons with an IQ less than 50, non-ambulatory and non-oral (feeders) are unemployable. Persons with an IQ between 50 and 79, those that ambulate with or without assistive

devices, and those with speech that is marginally intelligible can participate in sheltered employment. Those with and IQ greater than 80, have normal hand use, and intelligible speech can seek competitive employment. There are exceptions to these generalizations as technology can overcome physical limitations in the absence of mental impairment. The primary care doctor should assist the family in preparing for the future beyond childhood.

SUMMARY

- Cerebral palsy is a clinical syndrome rather than a specific disease entity.
- Diagnosis is based on persistent primitive reflexes, altered tone, and postural reactions.
- The etiology of cerebral palsy is multifactorial: including prenatal, neonatal and postnatal risk factors.
- Management of cerebral palsy is the management of the sequelae of the neurological insult like spasticity, scoliosis, cognitive impairment, and mobility impairment.
- Treatment options include physical interventions, pharmacological interventions and surgical ones.
- The psychosocial aspects of diagnosis and life with cerebral palsy impact the success the patient will have independent of the quality of medical management.

Acute Flaccid Paralysis

Sarbani Raha, Varjesh Udani

This is defined by the World Health Organization (WHO) as the sudden onset of weakness and floppiness in any part of the body in a child less than 15 years of age or paralysis in a person of any age in whom polio is suspected.¹

Components of the definition:

Acute: Rapid progression of paralysis from onset to maximum paralysis.

Flaccid: Loss of muscle tone, “floppy”—as opposed to spastic or rigid.

Paralysis: Weakness, loss of voluntary movement.

The case definition is broad in order to maximize sensitivity. Objective of AFP surveillance is to detect areas where polio transmission is still occurring, decide strategies to stop transmission and reliably confirm absence of transmission. The strategies used include:

- All cases should be reported immediately, irrespective of diagnosis within 6 months of onset.
- Stool specimen must be collected within 14 days though they can be collected up to 60 days after onset of paralysis. Common conditions besides poliomyelitis and related illnesses, that may present as AFP include: Guillain-Barré syndrome, acute transverse myelitis, traumatic neuritis, postdiphtheric polyneuritis, viral/parainfectious cranial neuritis.

The WHO reportable AFP presentations include flaccid mono, para, hemi and quadriplegias, isolated cranial neuropathies like facial palsy, isolated bulbar palsy and peripheral nerve palsies. Many of the latter are not reported as often as the limb weakness presentations.

NATIONAL POLIO SURVEILLANCE PROJECT¹

National polio surveillance project (NPSP) is a collaborative project of the government of India and the WHO and is managed by WHO. NPSP assists union and state governments with building and maintaining surveillance

for acute flaccid paralysis (AFP) and poliovirus. NPSP also assists with planning and monitoring of polio immunization activities aimed at eliminating polio from India.

Prior to October 1997, surveillance for polio in India was conducted through routine passive reporting by physicians of clinically suspected polio cases. Because surveillance was not designed to search for all cases of acute flaccid paralysis (AFP), and because active surveillance for AFP was not conducted, the ability of the system to detect polio cases was limited. In October 1997, the World Health Organization (WHO) and the Ministry of Health and Family Welfare, Government of India (GOI) recruited 59 surveillance medical officers (SMOs) to be trained and posted throughout the country to establish active AFP surveillance for polio eradication.

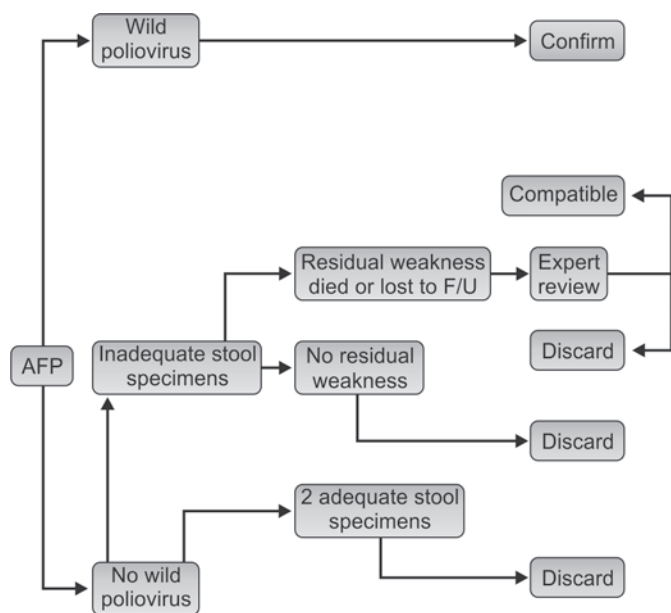

The four-pronged strategy has succeeded in eradicating polio from a large part of the world. This strategy involves maintaining high coverage of vaccination with at least three doses of live oral polio vaccine (OPV), providing supplemental rounds of vaccination, establishing an effective mechanism for the surveillance of AFP, and house-to-house OPV “mop-up” campaigns carried out at the final stage in a limited geographical region.

Polio situation: Globally only four countries are endemic for polio—India, Nigeria, Pakistan and Afghanistan. The P2 strain of poliovirus was eliminated in 1999.

From about 800 cases in 1998, confirmed polio cases have been reduced to 1 in 2011 (till 22 October) in India. In 2010, 42 wild poliovirus cases were confirmed; P1 strain-18 and P3 strain-24.

VIROLOGICAL CLASSIFICATION SCHEME

The Virological classification scheme (NPSP) scheme is used to classify polio cases on the basis of stool viral culture (Flow chart 1).

Flow chart 1: Classification of virological scheme

EFFECTIVENESS OF OPV

Between September 2002 and July 2005, type 1 wild poliovirus travelled from country to country, causing many outbreaks of polio. The number of cases ranged from 1 in Eritrea to 478 in Yemen. These cases had originated in Nigeria and India. In 13 of 21 countries, there were repeated outbreaks; in 8 of these 13 countries, transmission was later stopped. The countries that succeeded in halting the transmission had a median coverage with three doses of OPV of 83 percent, compared with 52 percent in the other 13 countries ($P = 0.001$). This experience suggests that the debate about ineffectiveness of the OPV is not valid and points towards failure to deliver the vaccine as the reason for continued virus transmission.²

ROLE OF INJECTABLE POLIO VACCINE (IPV)

Even with the eventual interruption of the transmission of wild poliovirus, outbreaks of paralytic polio will continue until the routine use of live vaccine is stopped. The public health benefits of OPV continue to outweigh the risks at the present time. This situation will reverse once transmission of wild virus is interrupted and it will be very difficult to eradicate polio using only OPV. The administration of the number of doses—sometimes as many as 10—required to confer the necessary immunity is a challenge. The possible solution may be that countries in which polio is endemic should organize three national immunization days with IPV with strategies like compulsory vaccination, which will give almost 100 percent protection to the children vaccinated. This may be followed by use of IPV in routine immunization programs to protect all successive birth cohorts. IPV in routine immunization would protect individual children while circulation of wild poliovirus

will be stopped with high coverage with OPV on national immunization days.²

VACCINE-DERIVED POLIOVIRUS (VDPV)

OPV contains a weakened version of poliovirus, activating an immune response in the body. A vaccinated person transmits the weakened virus to others, who also develop antibodies to polio, ultimately stopping transmission of poliovirus in a community. In very rare instances, the virus in the vaccine can mutate into a form that can paralyse—this is what is known as a vaccine-derived poliovirus or VDPV. If this virus regains the ability to circulate, it is called a circulating vaccine-derived poliovirus (cVDPV). As with naturally occurring poliovirus, the only protection against cVDPV is full vaccination. The important risk factors for cVDPV emergence include—low prevalence of immunity to poliovirus infection, low OPV coverage and poor sanitation—are likely to exist in populations where case ascertainment is incomplete.³

A fully-immunized population will be protected from all strains of poliovirus, whether wild or vaccine-derived.

Over the past 10 years, more than 10 billion doses of OPV have been administered to more than 2.5 billion children. As a result more than 3.5 million polio cases were prevented. During that time, 18 outbreaks of cVDPVs have occurred in 16 countries.

Reports of cVDPV outbreaks and references to other VDPV isolates have focused on the numbers of clinical cases involved in these episodes. Over some twenty years 114 virologically-confirmed cases of vaccine-derived polio have been reported worldwide. It is also possible that other vaccine-derived virus lineages have circulated for limited time periods, but failed to cause any clinical cases and were thus unrecognized. The risk of VDPV appearance and the incidence and spread of these infections will be important considerations for policies relating to the cessation of OPV, for future surveillance needs, and for planning for outbreak control in the future, including stockpiling vaccines.³

The small risk of VDPVs pales in significance to the tremendous public health benefits associated with OPV.

VACCINE-ASSOCIATED PARALYTIC POLIOMYELITIS (VAPP)

VAPP is defined as occurring in AFP cases if there is residual weakness 60 days after the onset of paralysis, if vaccine-related poliovirus was isolated from any stool sample, and if no wild poliovirus was isolated from any stool sample. A subset of recipient VAPP cases is defined as those VAPP cases with an interval of 4 to 40 days between the receipt of OPV and the onset of paralysis. One of the major risks of VAPP is host immunodeficiency especially hypogammaglobulinemia where virus excretion in stool can persist for a long time.

A report from India in 2002 estimates the following risk for VAPP cases: overall risk, 1 case per 4.1 to 4.6 million OPV doses administered; recipient risk, 1 case per 12.2 million; first-dose recipient risk, 1 case per 2.8 million; and subsequent-dose recipient risk, 1 case per 13.9 million.⁴ On this basis the estimated VAPP risk in India is evidently lower than that in other countries, notwithstanding the administration of multiple OPV doses to children in mass immunization campaigns. A reanalysis of the data however in 2003 by Mittal concluded that the risk of VAPP was 1 in 1.5 to 2 million doses,⁵ a rate which was higher than reported elsewhere in the world. Whatever the truth what is clear is that as wild polio infection declines AFP cases due to VDPV will persist as long as OPV continues. The ideal strategy would be to switch to IPV immunization over a few years after polio eradication.

In a study from Brazil⁶ where the last case of polio-myelitis was reported in 1989, a study of VAPP found that P2 and P3 virus were more commonly associated rather than P1. More than 95 percent were below 5 years of age and females were at higher risk. The majority of patients are vaccine recipients rather than contacts⁶ and constituted about 0.74 percent of all AFP reported. As in wild virus poliomyelitis a history of intramuscular injection was present in 30 percent of victims. Fever was prominent in 86 percent and >50 percent had monoplegia. In all, the illness was considered less severe than wild virus poliomyelitis. CSF showed pleocytosis in about 50 percent but interestingly an albumin-cytologic dissociation suggesting GBS was not uncommon.

GUILLAIN BARRÉ SYNDROME

Epidemiology

This has emerged as the major cause of AFP after the worldwide decline of poliomyelitis. The incidence <18 years is 0.34 to 1.34 cases per 100,000 per year⁷ which about half of that in adults. The average age is 4 to 8 years and is rare below the age of 2 years. Males appear more susceptible in all GBS variants. Unlike in Western countries, countries like China⁸ and Mexico⁹ seasonal peaks are seen with the acute motor axonal neuropathy (AMAN) variety of GBS. Acute inflammatory demyelinating neuropathy (AIDP) appears to lack this seasonal variation.

Mechanisms of Disease

The common demyelinating and axonal forms of the disease are both immune mediated involvement of both humoral and cell-mediated mechanisms. Triggers are mainly environmental pathogens like viruses—common ones noted include EB virus, CMV, hepatitis A and B, varicella, enteroviruses as well as *Mycoplasma pneumoniae*. *Campylobacter jejuni*, a gram-negative bacteria a leading cause of diarrhea appears particularly important as a trigger especially in the AMAN variant. Culture or serologic

evidence of preceding infection with this organism is seen in 17 to 66 percent of adult GBS.⁷ This association appears more common in Asian countries vis-à-vis western nations. In childhood developed countries like Germany report only 7.9 percent while developing countries like Mexico (44%) and India (28%) report higher figures probably linked to poor sanitation and close contact with animals.

Vaccinations like influenza, hepatitis B and less frequently the meningococcal vaccines confer an increased risk of GBS. The recent worldwide immunization with the H1N1 vaccine in 2009 resulted in an increased incidence of 0.8 cases per million doses.⁷

These triggers are believed to activate CD4⁺ helper-inducer T cells, which act against a variety of specific endogenous antigens, including myelin P-2, ganglioside GQ1b, GM1, and GT1a, etc. Resemblance of the triggering pathogens to antigens on peripheral nerves (i.e. molecular mimicry) leads to an overzealous autoimmune response mounted by T lymphocytes and macrophages.

Clinical Considerations

Typically, a progressive ascending symmetrical paralysis coming on over hours, days to a few weeks is the hallmark of GBS. Pain and refusal to walk are often presenting symptoms especially in preschool children (65%) and can often lead to misdiagnosis in as many as 68 percent in one study.¹⁰ Delay in treatment in preschoolers was up to a week in about a 1/4 of patients primarily because of misdiagnoses like arthralgias, myositis and other non-neurologic painful conditions.¹⁰ Autonomic manifestations are seen in up to a 1/3 with dizziness, hypertension, arrhythmia. Early areflexia especially the ankle jerk is usual though occasionally jerks may persist and rarely be exaggerated especially in the AMAN variant.

Evidence of radicular involvement is manifested by the straight leg raising sign (SLR) which is almost invariably positive. Bladder symptoms occur in about 10 percent but are usually transient. Cranial nerve involvement typically bifacial palsy occurs in half while bulbar palsy with dysphagia, drooling and dysphonia occurs less commonly. Ophthalmoplegia is exceptional except in the Miller-Fisher variant where ataxia and areflexia form the triad. The most dreaded complication is respiratory muscle weakness which can come on rapidly especially in the AMAN variant and leads to the occasional mortality.

AIDP and AMAN are the main types seen with segmental degeneration characterizing the former and axonal degeneration the latter. In western countries AIDP constitutes about 85 to 90 percent while in developing countries AMAN equals or exceeds AIDP, e.g. in China 70 percent are AMAN while in Mexico this pattern is seen in 49 percent vis-à-vis AIDP (32%).⁹ These differences are probably due to the high rates of preceding infections with *C. jejuni* in the developing world as elucidated earlier. *C. jejuni* typically leads to the AMAN variant which is often

associated with high anti-GM1A and anti-GD1A antibody titers.

Clinically the two syndromes could be remarkably similar though AMAN is probably more rapid in its evolution with higher grade of severity and more patients needing ventilation. The recent Mexican study did not find any major differences between the two variants. AMAN typically has little sensory manifestations while in AIDP dysesthesia is more common though objective sensory loss is mild or absent. The AMAN variant—acute motor and sensory axonal neuropathy is thought to be just a severe AMAN and some authorities have questioned the need to classify AMAN into its subtypes. Miller-Fisher syndrome typically has ophthalmoplegia, ataxia and areflexia and is seen in ~ 2 percent of all GBS.⁹ Generally, this is a milder disease with full rapid recovery. However, there are many patients with MFS/GBS overlap syndromes which can start as MFS and then develop into more generalized weakness. MFS and its variants are associated often with anti-GQ1B antibodies.

Diagnosis

It is imperative to reach a diagnosis as soon as possible. High CSF protein without a cellular response—so-called albumin-cytologic dissociation may take up to a week though changes are usually seen around 48 hours after onset. Sometimes there is a cellular response of up to 50 cells which can suggest a viral etiology GBS associated with HIV typically has a significant CSF pleocytosis. Nerve conduction studies peak in the second week though some specific changes may be seen in the first week like absence of late responses, etc. Hence, the problem with both CSF and NCV is that they may be normal in the first week of illness.

Recently spinal and sometimes cranial contrast MRI has gained popularity as changes are seen within 2 days in >90 percent of children.^{11,12} Typically the ventral roots of the cauda equine show enhancement though it is more common to have the more nonspecific both anterior and posterior root enhancement. Cranial nerves may also show enhancement fairly commonly—typically the abducens, oculomotor and facial nerves.

Antibodies to different ganglioside antigens have different sensitivities in different regions. It appears to be uncommon in western countries like Germany¹³ while is seen in up to 44 percent in Asian patients including India.¹⁴ This positivity is associated with previous diarrhea (presumably *C. jejuni* associated), AMAN variant and slower recovery times.^{14,15}

Though these antibody tests help in understanding GBS and its subtypes they really do not help in the diagnosis in the acute stage.

Treatment

Plasma exchange and IVIG have been shown to be equally effective in hastening recovery in all GBS including childhood GBS.¹⁶ However, the ease of administration of IVIG as well as less adverse effects makes this the first line treatment in childhood GBS. Studies have typically involved more severely affected patients and the dosage used has been high dose 2 gm/kg. Whether milder affected ambulant patients benefit from IVIG is not really studied. Also, in a resource-poor country like ours, we need to study whether lower doses of IVIG would suffice. It is not known whether IVIG given later than 2 weeks after onset of disease would hasten recovery as all studies have used early treatment. Corticosteroids have not been shown to hasten recovery and oral steroids may actually delay recovery.¹⁷

Prognosis

In general, the outcome in children is excellent. Mortality is unusual nowadays with modern intensive care. However in developing countries the mortality is still reported about 1 in 10.¹⁸

Though the AMAN variant reaches a more severe disability stage than AIDP and has a higher rate of respiratory failure needing ventilation, the final outcome at 12 months is excellent in both groups.¹⁸

AFP DUE TO OTHER VIRUSES

Nonpolio enteroviral (NPEV) are common isolates from AFP patients ranging from 20 to 72 percent of patients. It is difficult to be sure whether they represent background viral circulation or actually are causative of the AFP. In a study from the Americas¹⁹ 40 percent were clinically diagnosed as GBS and NPEV isolation was greater in older children. Fever, residual paralysis and atrophy were less likely than wild poliovirus positive cases and the paralysis was more often ascending (32 vs 18%) when compared to wild virus poliomyelitis. In a more recent study²⁰ from Pakistan, 60 percent of NPEV-associated AFP had fever at onset, about 2/3 had asymmetrical paralysis and the peak of the illness was rapid as in wild virus poliomyelitis. Twelve percent patients died and 39 percent had residual paralysis suggesting a much less benign course than the American study. Certain specific enteroviruses like EV 71 and coxsackie A7 have been clearly linked to AFP.

Japanese B virus, rabies and west Nile virus sometimes present as AFP.

ACUTE TRANSVERSE MYELITIS

This has an incidence of 1 to 8 per million per year and can occur alone or be a part of neuromyelitis optica,

multiple sclerosis or acute disseminated encephalomyelitis. The word “transverse” is often a misnomer as though the clinical findings suggest a single level often the MRI shows significant involvement. Mean age is ~ 8 years.²¹ Typical diagnostic clues include a history of preceding infection/ vaccination in about 2/3rd of the cases, back pain and fairly rapid progression of paraplegia/ quadriplegia (mean 3.9 days).²¹ It has been described after the many agents like measles, varicella, mumps, hepatitis, *Mycoplasma* and often has associated antibodies include anti GM1 ganglioside antibodies,²¹ antiphospholipid antibodies and others.

Sensory loss and persistent sphincteric involvement differentiates this from poliomyelitis like illnesses and GBS. Initial hypotonia and areflexia soon give way to spasticity and hyperreflexia. CSF may show increased protein with lymphocytic pleocytosis or can be normal. MRI makes the diagnosis with usually long segment cervicodorsal hyperintensity with occasional contrast enhancement. Concurrent brain MRI might show white matter lesions when the myelitis is part of an ADEM syndrome. Neuromyelitis optica comes with long-segment myelitis (>3 vertebral segments) and the optic neuritis may precede or follow the myelitis by up to 1 year. NMO-IgG antibodies help make his diagnosis which can be recurrent symptoms and would need ongoing immune-modulatory treatments. Multiple sclerosis presenting as myelitis is extremely rare and it does occur it usually is a partial lesion involving <3 segments.

Treatment is best with intravenous high dose methylprednisolone (30 mg/kg/day) for 3 to 5 days with oral steroids thereafter for 4 weeks. Outcome is fairly good in ~ 60 percent of cases though some children remain wheelchair bound. Motor symptoms improve earlier than bladder dysfunction.

Other disorders rarely presenting as AFP include snake-bite envenomation, myasthenic crisis, hypercalcemia/hypermagnesemia, hypokalemic/hyperkalemic periodic paralysis, organophosphorus poisoning and acute intermittent porphyria.

Stroke in Children

KS Rana

INTRODUCTION

Childhood stroke is rarely considered as a significant medical problem in developing countries. Stroke in children is not rare and the burden of disability related to the neurological impairment from this disorder is significant. The incidence of childhood stroke is increasing and currently exceeds six per lakh children per year and adverse outcome including death in 10 to 40 percent children in the developed world.^{1,2} True impact of childhood stroke in developing countries is unknown and may be more because of prevailing risk factors like infections, anemia, dehydration, etc. Adults with stroke have benefited from the evidence based treatment trials but such trials have not been conducted in children with stroke. There are considerable differences in the vascular, coagulation and nervous system in children, compared to adults. Pathophysiology, risk factors and clinical features have age related differences. The diagnosis of stroke in children is often delayed due to the relative rarity of the disorder and lack of acquaintance with the diagnosis. The potential for recovery from the stroke in children may be different because of increased plasticity in the immature brain. Present chapter will cover children beyond neonatal period.

TYPES OF STROKE

Acute ischemic arterial stroke, acute venous stroke +/- hemorrhage, primary intracranial hemorrhage (intraparenchymal, intraventricular and subarachnoid)

RISK FACTORS

Common risk factors for ischemic stroke in children are arteriopathies (53%), cardiac disorders (31%), infections (24%), acute systemic disorders (22%) and prothrombotic states (13%). The prevalence of risk factors varied

with age/sex and geographical location. Arteriopathies are more common in children aged five to nine years (66%), acute systemic infections in less than five years of age (31%) and prothrombotic states in children more than 10 years of age.³ In Asia, arteriopathies, cardiac disorders and systemic infections contribute for majority of childhood stroke, whereas chronic head and neck disorders and prothrombotic states are the main risk factors for stroke in Europe and America. Posterior circulation stroke are more common in boys. Almost 50 percent children have multiple risk factors.³ Underlying causes for hemorrhagic stroke are arteriovenous malformations and coagulopathies. In developing countries more than one-third cases have no identifiable cause as compared to 10 percent in the developed world.³ Identifiable risk factors for childhood stroke are given in Table 1.⁴⁻⁷

CLINICAL PRESENTATION

The World Health Organization (WHO) definition of stroke is 'rapidly developing clinical signs of focal (or global) disturbances of cerebral function, with symptoms lasting more than 24 hours or longer, or leading to death, with no apparent cause other than of vascular origin'. Patients whose signs resolve within 24 hours have transient ischemic attacks (TIA), but many of children with TIA have recent cerebral infarction or hemorrhage on imaging.⁸

Clinical presentation depends upon the type of stroke. In arterial ischemic stroke (AIS) of anterior circulation, acute hemiparesis is seen in more than two-thirds. Altered sensorium, raised intracranial pressure and impending herniation symptoms are observed in large middle cerebral artery (MCA) territory infarction, vertebrobasilar circulation stroke, intracranial hemorrhage and venous sinus thrombosis (VST). Seizures and headache are common in VST. In posterior circulation stroke, other presenting symptoms are cranial nerves deficit with cross

Table 1: Risk factors for childhood stroke

<i>Cardiovascular</i>	
Congenital heart diseases	Complex congenital heart diseases, septal defects, aortic/mitral stenosis, coarctation of aorta, mitral valve prolapse, patent foramen ovale.
Acquired heart diseases	Rheumatic heart disease, prosthetic valve, infective endocarditis, cardiomyopathy, arrhythmias, cardiac surgery.
Systemic vascular diseases	Hypertension, dehydration, diabetes, atherosclerosis, hypernatremia.
<i>Vasculitis</i>	Infections (meningitis, systemic infections, varicella, acquired immunodeficiency syndrome, sinusitis, pharyngitis, otitis media), kawasaki disease, systemic lupus erythematosus, other rheumatic disorders.
<i>Vasculopathies</i>	Moyamoya, Ehler-Danlos syndrome, Fabry disease, neurofibromatosis
<i>Hematological disorders</i>	Hemoglobinopathies (sickle cell), polycythemia, anemia, thrombocytosis, thrombocytopenia, disseminated intravascular coagulation (DIC), leukemia, Vit K deficiency, acquired and congenital hemolytic anemia, Protein C and S deficiency, antithrombin-III deficiency, factor V G1691A mutation, prothrombin G20210A variant, elevated protein (A), dysfibrinogenemia, dysplasminogenemia, heparin cofactor-II deficiency, factor XII deficiency, lupus anticoagulant, anticardiolipin antibodies, Antiphospholipid antibodies, congenital coagulation defects, anticoagulants
<i>Metabolic disorders</i>	Homocystinuria, organic academia, mitochondrial cytopathies, ornithine transcarbamylase deficiency.
<i>Vasoplastic disorders</i>	Migraine, alternating hemiplegia, vasospasm.
<i>Vascular anomalies</i>	Arteriovenous malformation, hypoplastic/stenotic vessels, intracranial aneurysm, fibromascular dysplasia, cavernous angioma, hereditary-hemorrhagic telangiectasia, Sturge-Weber syndrome.
<i>Traumatic</i>	Child abuse, congenital bony anomalies of neck region, fat/air embolism, post traumatic arterial dissection, blunt cervical injury, trivial head injury, intraoral trauma, craniovertebral junction anomalies.
<i>Others</i>	Drugs like L asparaginase, oral contraceptives, cocaine/amphetamines, Down syndrome, arterial catheterization, post irradiation, bone marrow transplant, nephrotic syndrome, celiac disease, solid tumors, VP shunt, recent head surgery, and progeria.

hemiparesis, vertigo, ataxia, dysarthria and neck pain. Several classical syndromes (mesencephalic, pontine and medullary), based on the involvement of vessel or its branches affecting the brainstem have been described in posterior circulation stroke. Spinal cord stroke was rarely diagnosed until emergency MRI of the spinal cord became the norm. Patients in spinal cord stroke present with sudden onset of flaccid paraparesis or quadriplegia, loss of sensations and autonomic disturbances mainly bladder and bowel dysfunction. Silent infarction may be demonstrated on MRI in 'at risk' population.⁹

Differential Diagnosis of Acute Focal Neurological Deficit

Stroke mimics include acute disseminated encephalomyelitis (ADEM), reversible posterior leukoencephalopathy (PRES), poststreptococcal inflammation, and metabolic stroke like mitochondrial encephalopathy, hemiplegic migraine, border zone ischemia, epilepsy, brain tumors, focal encephalitis like herpes simplex, alternating hemiplegia and some of neuro-degenerative conditions (Fabry disease). Around 15 to 20 percent of children presenting with acute neurological deficit have a nonvascular cause.¹⁰ There are often clinical features suggestive of these disorders and infarct on neuroimaging may also not be in the vascular territory. In ADEM, there is predominant white matter involvement. In hemiplegic migraine, electroencephalography (EEG) shows

unilateral slow background activity and epileptic discharges in epilepsy. In PRES, involvement is predominantly of posterior white matter and edema is vasogenic and not cytotoxic as seen in the stroke.

DIAGNOSTIC APPROACH

Aim of the diagnostic evaluation is to confirm the presence of stroke, identify its cause and eliminate other causes of acute neurological dysfunction. Detection of the cause of cerebrovascular disease is particularly important in children, because the recurrence risk is determined largely by the underlying cause. A child at risk for stroke faces the increased susceptibility and treatment of risk factors relatively for a long life than in adults.

First step in the evaluation is to do emergency neuroimaging to confirm the stroke and type of stroke (Figs 1A to C). It also detects the vascular distribution of stroke and excludes other causes of neurological deficit. Neuroimaging in childhood cerebral stroke has dramatically improved over the last decade. It should also include the neck for arterial dissection and other local causes. CT scanning has been the primary modality of brain imaging in acute stroke but has been surpassed by MRI techniques such as diffusion and perfusion sequences. Diffusion MRI can detect ischemic changes during hyperacute phase (first six hours after symptoms onset) when conventional MRI (T1 and T2 weighted) is normal.¹¹ CT remains the modality of

Figs 1A to C: (A) Contrast CT brain showing large hypodense lesion with mass effect no enhancement and (Right MCA infarct), (B) Noncontrast CT brain showing hyperdense lesion left frontal lobe (Fresh parenchymal hemorrhage); (C) MRI brain (Diffusion weighted image) in hyperacute stage of arterial ischemic infarct (Left MCA territory)

choice for detection of acute intracranial hemorrhage. Although MRI is more sensitive than CT in imaging acute stroke, CT is still performed as it is more widely available and affordable. One of the main disadvantage of CT is that ischemic stroke is often not obvious on CT with in first 24 hours. It can also miss venous sinus thrombosis and posterior circulation stroke. Magnetic resonance angiography (MRA) and venography (MRV) sequences use the inherent contrast of flowing blood and do not require the contrast. MRA and MRV sequences are used to delineate arterial and venous system and to detect any structural and flow abnormality. Conventional cerebral angiography is reserved for children with stroke with no obvious etiology provided by clinical assessment, investigations for various risk factors and in children with stroke with normal MRA.

Step two in the evaluation is to detect the underlying risk factor. There are numerous risk factors for stroke in children, but it is unnecessary to consider all of them in each child. While many children have multiple risk factors but it is not necessary to investigate the rare causes when the etiology is fairly obvious from the beginning as in case of heart disease and sickle cell disease. Diagnostic evaluation should be done in stages, with the next step influenced by the previous result. Noninvasive, low cost and high yield tests should be done first.

A complete blood count, peripheral smear, erythrocyte sedimentation rate (ESR), urine routine examination can provides clue to many conditions. Hemoglobin electrophoresis should be done on patients at risk of hemoglobinopathy. Coagulation profile (PT, PTT, and INR) is helpful in both

ischemic and hemorrhagic stroke. Clotting factors assay is done in intracranial hemorrhage when their deficiency is suspected. Blood sugar, lipid profile and serum proteins are also included in the initial workup.

Complete cardiac evaluation including X-ray chest, ambulatory cardiac monitoring, electrocardiography and echocardiography to be done in suspected cardiovascular etiology. Their yield is low if cardiac examination is normal. Lumbar puncture should be considered in any child with focal neurological deficit who has no mass effect and in whom the evaluation has not established any cause. Cerebrospinal fluid (CSF) examination is essential in stroke with unexplained fever or signs of central nervous system infection. Chronic infections like tuberculosis and syphilis can also manifest as stroke and should be evaluated when suspected. Head and neck examination should be done by expert for excluding local causes like otitis media and sinusitis. X-ray and MRI neck in suspected C-V junction and vertebral anomalies. Color carotid Doppler is done to look for flow abnormalities.

If the above evaluation does not establish a cause, include more uncommon risk factors such as metabolic and prothrombotic states.¹² Look for serum levels of protein C, S, antithrombin III, lipoprotein[a], fasting homocysteine, fibrinogen, plasminogen, factor VIIIc, factor XI, lupus anticoagulant, antiphospholipid antibodies, Factor V G1691A, prothrombin G20210A and methylene tetrahydrofolate reductase gene mutation (MTHFR C677T). For suspected metabolic causes of stroke in children, CSF and arterial lactate, blood ammonia, amino acids, fatty

acids and organic acid estimation are required in blood and urine. To prevent results of protein based assays from being affected by the acute thrombotic onset, blood samples should be taken at least three to six months after thrombotic episode. Homocystein and lipoprotein [a] levels should be obtained during fasting state. For all plasma based assays a clotting abnormality should be labeled as abnormal in at least two different samples at different times. Anticoagulants should be stopped at least seven to ten days before estimating plasma based assays.

ACUTE MANAGEMENT

General Care

Even in the present era majority of stroke children have irreversible focal brain damage by the time of their presentation to hospital, and therapeutic effort is usually concentrated on rehabilitation and the prevention of recurrence. Emergency management for raised intracranial pressure and impending herniation should be done under appropriate protocol. Priority is to maintain airway, cardiovascular status, hydration and blood pressure. Children with deteriorating consciousness should be ventilated. Management of seizures in acute setting should be according to appropriate protocol. Neuroprotective measures like preventing fever and maintaining body temperature just below 37°C.

Emergency Neuroimaging

CT brain remains the modality of choice in acute stroke but if emergency MRI is available, despite the need for general anesthesia in most cases, it has advantages over CT as, in addition to the essential exclusion of hemorrhage, ischemia can be documented within minutes, using diffusion-weighted imaging. MRI is also superior over CT in posterior circulation stroke and neck vessels. MRA and MRV sequences further help in establishing vascular pathology.

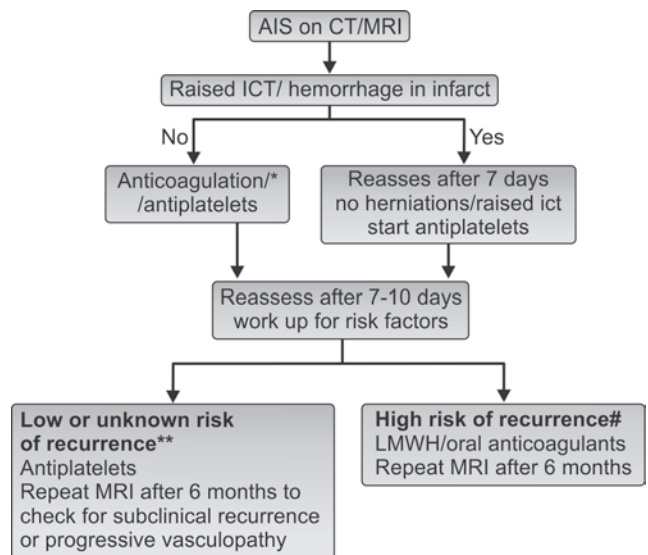

Specific Measures (Flow Chart 1A to C)

In hemorrhagic stroke, the main priorities are to prevent life threatening herniation, to reverse any thrombocytopenia or coagulopathy, to exclude STV, and treat any associated vasospasm as in subarachnoid hemorrhage, with volume expanders. Mass effect can be treated with hypertonic saline, mannitol or hyperventilation (PaCO₂ 35 to 45 mm Hg). Life-threatening herniation may benefit from craniotomy and hematoma drainage. Underlying coagulopathy is common in infants. Hemorrhagic disease of the newborn should be treated with vitamin K and DIC with fresh frozen plasma. Fresh platelet transfusion is required in thrombocytopenia and factor VIII in hemophilia.

Almost 50 percent children presenting with ischemic stroke or sinovenous thrombosis have a known underlying risk factor particularly sickle cell disease, anemia, cardiac disease, systemic illness and infection. Emergency management in them includes antibiotics in infections, exchange transfusion in sickle cell disease and anticoagulation heparin or low molecular weight heparin (1 to 1.5 mg/kg/12 hourly) in STV, extracranial vascular dissection, major prothrombotic states and underlying heart disease with high risk for recurrence of stroke. Contraindications for anticoagulation include: platelets less than 50,000/cu mm; recent intracranial hemorrhage; active systemic hemorrhage; major surgery in last 24 hours and uncontrolled severe hypertension. Aspirin in the dose of 3 to 5 mg/kg/day is indicated in remaining AIS.

Currently two to four percent children presenting with stroke receive thrombolysis with tissue plasminogen activator (tPA), but there have been no randomized controlled trials which address the use of tPA in the treatment of stroke in children.¹³ Although some children

Flow chart 1A: Management of arterial ischemic stroke

AIS, arterial ischemic stroke; CT, computerized tomography; MRI, magnetic resonance imaging; ICT, intracranial tension; LMWH, low molecular weight heparin.

* Anticoagulants for extracranial vascular dissection/cardioembolism/major prothrombotic states.

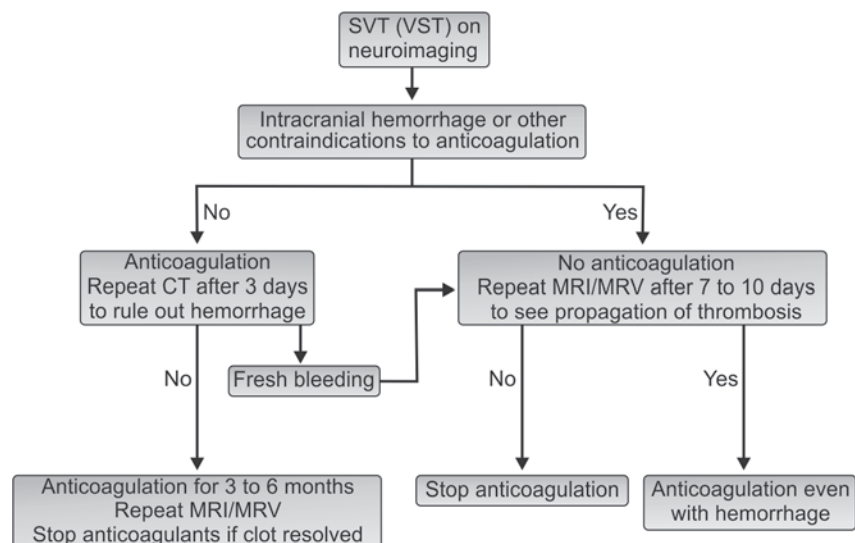

** Low or unknown risk of recurrence: Idiopathic stroke, cerebral arteriopathy, congenital heart disease like foramen ovale, mild prothrombotic states.

High risk of recurrence: Recurrent strokes or TIA while on aspirin, extra-cranial arterial dissection, severe arterial stenosis (>90%), high risk cardiac disease for recurrence, major prothrombotic states.

(a) After six months, anticoagulation and antiplatelets are stopped if recurrence risk is low/unknown.

(b) Exchange transfusion in case of sickle cell disease.

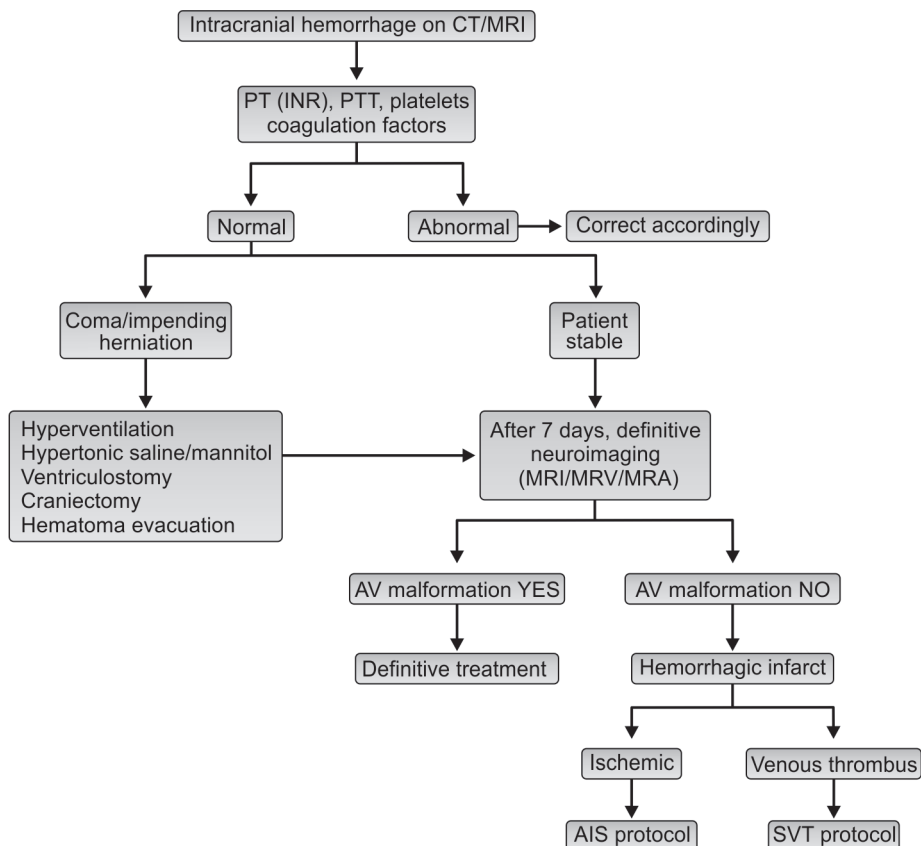

(c) Follow-up in stroke clinic every three to six months.

Flow chart 1B: Management of sinovenous thrombosis

SVT: sinovenous thrombosis; VST: venous sinus thrombosis; MRV: magnetic resonance venography; MRI: magnetic resonance imaging.

(a) Treat raised ICT, hydrocephalus and seizures as per standard protocols.

(b) In life-threatening situations surgical craniectomy may be considered.

Flow chart 1C: Management of hemorrhagic stroke

PT: prothrombin time; PTT: partial thromboplastin time; INR: international normalization ratio, AIS: arterial ischemic stroke; SVT: sinovenous thrombosis, MRA: magnetic resonance angiography; MRV: magnetic resonance venography; AV: arteriovenous.

can present to hospital within three hours, because rarity of stroke, low sensitivity of CT for acute infarction and the wide differential in this age group, the diagnosis of arterial occlusion is rarely made. In addition mortality in this age group is not very high and majority of such children can lead independent life as adult. It is therefore difficult to see a major role for thrombolysis in children at least in the present.

RECURRENCE AND PREVENTION

The overall risk of recurrence in arterial ischemic stroke is 10 to 25 percent.¹⁴ It may be as low as six percent in those with no risk factor or as high as 66 percent in moyamoya and 92 percent in children with sickle cell disease, who receive no treatment.¹⁵ Silent reinfarction is typical of sickle cell disease with an incidence of seven per hundred patients per year.¹⁶ Recurrence risk is six to 20 percent in cerebral venous thrombosis. Whilst there is no direct evidence that either antiplatelet agents or anticoagulants reduce the risk of recurrence in children with first AIS, both are commonly prescribed and advocated in published guidelines. Current clinical guidelines recommend antiplatelet doses of aspirin (3-5 mg/kg/day) in majority of children presenting with first AIS. Indications for long term anticoagulants (usually with warfarin 0.1 mg to 0.2 mg/kg/day) include patients with cardioembolic stroke, extracranial dissection, prothrombotic states like protein C, S deficiency and cerebral venous thrombosis. Dose of warfarin is adjusted according to INR and standard treatment of thrombosis is, maintaining INR 2.0 to 3.0. There may be a role of anticoagulation in children who develop stroke despite adequate antiplatelet therapy. Duration of the preventive treatment depends upon underlying risk factors. In children with low or unknown risk factors it is usually recommended for six months. Surgical revascularization is widely used as a treatment to prevent recurrence in moyamoya disease. Blood transfusion significantly reduces the risk of recurrent AIS in sickle cell diseases. The aim of regular transfusion is to maintain HbS percent below 25 percent and to maintain hemoglobin between 10 to 14 g/dl. Bone marrow transplant is an indication in sickle cell disease in many developed countries and it stabilizes imaging abnormalities in SCD. Closing foramen ovale to prevent stroke recurrence is controversial. Risk of stroke recurrence in foramen ovale depends upon the degree of right to left shunting and the risks and benefits of closure should be considered on an individual basis. Folate supplementation is advised to children with hyperhomocysteinemia and those who are homozygous for MTHFR C677T. Blood pressure should be monitored. Suggestion regarding diet, smoking and regular exercise is important. Children with risk of recurrence should be advised to maintain hydration, prompt treatment of fever and infections.

Rehabilitation

Rehabilitation needs multidisciplinary team to rehabilitate the child with stroke and to support the family. Aim is to restore and promote further development of optimal functional skills. It should be home and community based. Growth, development and occupations of the child (i.e. usual activities and participation) should be the central to practice.

The Autistic Spectrum Disorders

RK Sabharwal

INTRODUCTION

Autism is an etiologically and clinically heterogeneous group of disorders, collectively referred to as the “autism spectrum disorders (ASDs)”. The concept of autism in children was first introduced by Leo Kanner in his seminal paper published in 1943. He described a pattern of behavior he called ‘early infantile autism’ characterized by severe impairment of social interaction and communication, and intense resistance to change. For decades after this publication, childhood autism was considered to be a rare condition.¹ Before and for years after Kanner’s first paper on his syndrome, autistic conditions were often diagnosed as childhood schizophrenia. A major change in the concept of childhood autism was evident in DSM-III. (American Psychiatric Association, 1980).² This introduced the term ‘pervasive developmental disorders’ (PDDs) as a general category, thus acknowledging the shift in the concept of autism from a psychiatric to a developmental disorder.

In 1944, Hans Asperger identified in four boys a pattern of behavior and abilities that he called “autistic psychopathy”. The pattern included *a lack of empathy*, little ability to form friendships, one-sided conversations, intense absorption in a special interest, and clumsy movements. Asperger called these children as *little professors* because of their ability to talk about their favorite subject in great details.³

Autism, also called infantile autism or autistic disorder, is a lifelong disorder that causes abnormal neurological development. It is one of five pervasive development disorders (PDDs) that also include Asperger’s syndrome (milder disorder with normal language), childhood disintegrative disorder, Rett disorder (severe disorder in female children), and pervasive development disorder-not otherwise specified (PDD-NOS). The severity of autism’s deficits is extremely variable. Therefore, the term autism spectrum disorders (ASDs), or “the autisms,” is appropriate because it denotes

a bell-shaped curve of impairment.⁴ While the autism spectrum disorders (ASDs) are also termed as pervasive developmental disorders (PDDs); the term “autism” or autistic disorder (AD) should be used for the classic pro-typical cases. Asperger’s syndrome refers to ASD children in whom speech is not delayed and whose IQ is at least 70.⁴ The acronym PDD-NOS (PDD not otherwise specified) applies to ASD children who do not fulfill criteria for Asperger’s syndrome or AD; these children form a heterogeneous group generally less severely affected than those who have AD. There are three key manifestations of autism:

1. Impaired sociability, empathy, and ability to read other people’s moods and intentions, with resulting inadequate or inappropriate social interactions
2. Rigidity and perseveration, including both stereotypes (purposeless repetitive movements and activities), the need for sameness, and resistance to change
3. Impaired language, communication, and imaginative play.

EPIDEMIOLOGY

Studies carried out in the late 1990s and the present century reported annual rises in incidence of autism in pre-school children, based on age of diagnosis, and increases in the age-specific prevalence rates in children. Prevalence rates of up to 60 per 10,000 for autism and even more for the whole autistic spectrum were reported. Reasons for this increase includes: changes in diagnostic criteria, development of the concept of the wide autistic spectrum, different methods used in studies, growing awareness and knowledge among parents and professional workers and the development of specialist services, as well as the possibility of a true increase in numbers. A recent surveillance study reported a 57 percent average increase in the number of autism diagnoses in specified regions of the United States from 2002 to 2006, and estimated the current prevalence to be one in 110 children.⁵ Although these

studies reflect a 10-fold increase from studies published a half-century ago that chiefly targeted AD alone, most of the newer studies also included individuals with Asperger's syndrome and PDD-NOS. Wide variations in the incidence of Rett's syndrome have been reported among various countries. Rates as high as 1 per 10,000 live female births have been reported.

ENVIRONMENTAL

In light of current evidence, it seems likely that the etiology of autism 'involves complex interactions between environmental factors and genetic mutations controlling either:

- the patterning of neuronal populations critical for the control of inhibition/excitation in the cortex, and/or
- the synaptic assembly of these excitatory and inhibitory neuronal networks and/or the neuronal networks involved in large-scale cortical neuromodulation (Fig. 1)".

An important concept in developmental neurobiology is that genes involved in the development of the CNS are extremely pleiotropic, i.e. several important genes involved in the early patterning and specification of neuronal subpopulations also act later in development to regulate the proper synaptic assembly of the same or other neuronal populations. Therefore, a mutation in one of the genes reviewed above will undoubtedly have many complex, non-redundant functions during development of the CNS that could lead to a divergent and complex neuropathology such as autism.⁷

Sex

Sex bias for PDD is significant. Autism and PDD-NOS may be 5 times more common in boys than in girls. Asperger's syndrome may be 10 times more common in boys than in girls. Only Rett's syndrome affects more girls than boys; in fact, Rett's syndrome is rarely diagnosed in boys. However,

new molecular testing for Rett's syndrome indicates that the incidence of the condition is greater in boys than previously reported. Finally, the male predominance noted above also suggests a genetic role in the inheritance of autism.

Race/Ethnicity

Identified ASD prevalence also varied by race/ethnicity, with some sites showing higher ASD prevalence estimates among non-Hispanic white children than among non-Hispanic black children and Hispanic children. Considerable variability has been reported across studies in the racial disparities of ASDs.

Prenatal, Perinatal and Neonatal Factors

The incidence of autistic disorder in survivors of neonatal intensive care appears to be elevated. It has been hypothesized that pregnancy, delivery, or neonatal complications may act through independent etiologic pathways to increase the risk of autism or may interact with a genetic disposition to increase the risk by interfering at critical times in the developmental process.⁸ High maternal age (≥ 35 years), multiparity (≥ 4), daily smoking in early pregnancy, were associated with increased risk for autism in the univariate analyses. Increased risks of autism were also found in pregnancies complicated by hypertensive diseases, bleeding, and a number of delivery and infant characteristics, including cesarean delivery, preterm birth (≤ 36 weeks), low birth-weight ($\leq 2,500$ g), small or large size for gestational age, low Apgar score (0–6) at 5 minutes, and congenital malformations.

Genetics

New technology, especially array chromosomal genomic hybridization, has both increased the identification of putative autism genes and raised to approximately 25

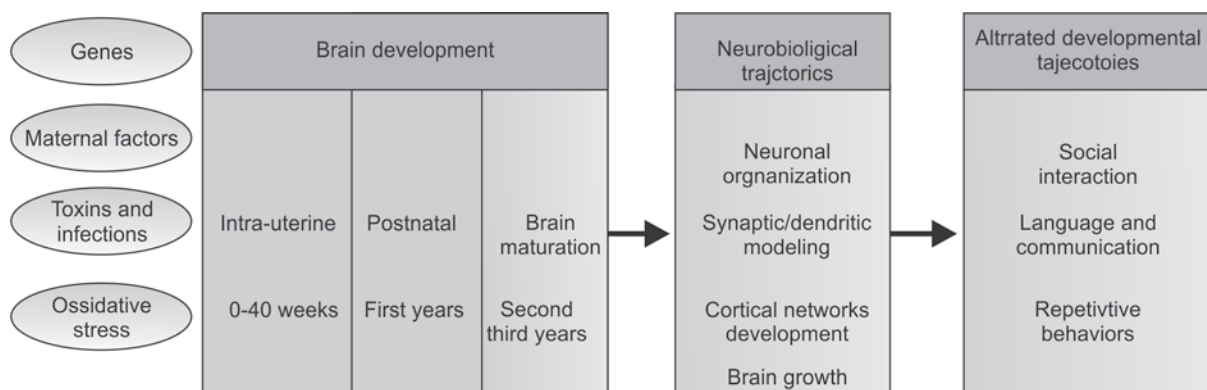

Fig. 1: Genetic and epigenetic factors involved in the pathogenesis of autism. Interactions between multiple genes and environmental factors, such as intrauterine infections, alcohol/ toxins exposure, and obstetrical sub optimality, can influence intrauterine and early postnatal brain development and disrupt crucial neurobiological pathways, from neuronal migration and cortical organization to synaptic and dendritic conformation, resulting in alterations of neurobehavioral trajectories that are involved in the pathogenesis of ASD.⁶

percent, the percentage of children for whom autism related genetic change can be identified.⁹ Using standard medical genetic evaluation techniques, a genetic cause can be identified in 20–25 percent of children on the autism spectrum. This number has increased with the use of array comparative genomic hybridization (aCGH) also called chromosomal microarrays (CMAs). Identified genetic causes of autism can be classified as the cytogenetically visible chromosomal abnormalities (5%), copy number variants (CNVs) (i.e. submicroscopic deletions). The most common autism related CNVs are the 15q11.2-11.3 duplications, similar to duplications revealed by FISH, and reciprocal 16p11.2 microdeletions and duplications (10–20%), and single-gene disorders (5%). Although at least 1 autism linked abnormality has been found on almost every chromosome, sites on a few chromosomes (X, 2, 3, 7, 15, 17, and 22) seem to be more promising than others.

Single Gene Disorders

Autism or autistic features have been reported in children with many other single gene disorders. Most are associated with severe mental retardation and significant dysmorphology, and the children are rarely referred with an initial question of autism. Autism in these cases is often referred to as “syndromic autism”.

- *Fragile X syndrome*: Approximately 1 to 3 percent of children with a diagnosis of autism diagnosis can be shown to have fragile X syndrome. At least half of children with fragile X syndrome exhibit some autistic behaviors, such as avoidance of eye contact, language delays, repetitive behaviors, sleep disturbances, tantrums, self injurious behaviors, hyperactivity, impulsiveness, inattention, and sound sensitivities.
- *Tuberous sclerosis complex*: About 25 to 50 percent of mentally retarded individuals with tuberous sclerosis complex (TSC) fulfill autism diagnostic criteria. Early onset infantile spasms and temporal lobe tubers on magnetic resonance imaging (MRI) examination increase the chance that children with TSC2 mutations will also develop autism, molecular genetic testing for the two causative genes, TSC1 and TSC2, is clinically available. Recurrence risks for families with a child with autism due to TSC may be significantly higher than for families with autism of unknown cause.
- Others:
 - Mitochondrial disorders
 - Adenylosuccinate lyase deficiency
 - Creatine deficiency syndromes
 - Smith-Lemli-Opitz syndrome
 - Angelman syndrome
 - Duchenne muscular dystrophy
 - Sotos syndrome
 - Neurofibromatosis 1, hypomelanosis of Ito, etc.

ETIOLOGY

Autism is not a disease, that is, it is not a condition with a well-defined single etiology. It is a behaviorally defined syndrome of neurological dysfunction. The evidence for a genetic contribution has come from twin and family studies. Concordance rates for monozygotic twins are significantly higher than for dizygotic twins, and heritability is more than 90 percent. Family studies have consistently shown that, although the actual recurrence risks are low (2-7%), the relative risk is 50 to 200 times higher than the population prevalence.¹⁰

In the vast majority of cases, autism has no evident cause. One can safely assume that etiology in such cases consists of a mixture of undetected acquired causes, non-syndromic genetic causes (new mutations, single cases of recessive inheritance, etc.) and perhaps in a majority polygenic inheritance or inheritance of a susceptibility gene to otherwise innocuous environmental factors.

An etiology may be found in 10 to 20 percent of children with autism (Table 1).

CLINICAL SYMPTOMATOLOGY

The behavioral features of autism involve affectation of abilities that can be remembered by the mnemonic SCALD (sociability, communication, affect, language and drive). Onset of autism is prior to 3 years of age and may be gradual with pre-existing evidence of difficulties in socialization and communication or may consist of an “autistic regression” in

Table 1: Some etiologies of autism

Unknown

Currently the most frequent situation

Genetic

- Known single gene defects, e.g. PKU, tuberous sclerosis
- Defined chromosome anomalies, e.g. fragile-X, Angelman, Down, Williams syndromes, etc.
- Syndromes with suspected genetic etiology, e.g. Cornelia de Lange, Joubert syndromes
- Polygenic inheritance (currently favored)
- Inheritance of enhanced susceptibility to some environmental factor
- Single Mendelian dominant, recessive, X-linked gene defects (rare?)

Non-genetic

- Intrauterine infection, e.g. rubella, CMV
- Brain malformation/ anomaly, e.g. hydrocephalus, some neuronal migration defects, Moebius syndrome
- Postnatal brain damage, e.g. bilateral herpes simplex, bilateral hippocampal sclerosis, severe ischemia/ anoxia
- Early malignant epileptic encephalopathy, e.g. infantile spasms, Lennox-Gastaut syndrome.

a child who had previous normal development, the latter occurring in 20 to 40 percent of this population.

The category of non-autistic PDD includes Asperger's disorder. This is a group of children with less severe impairment of socialization who has difficulty in interpreting and using social cues and has naïve/pedantic language use. Language is superficially normal but is still associated with problems of abstraction, interpretation, and pragmatics. By definition, all have normal or near normal intelligence. Whether this is a milder manifestation of autistic disorder or a separate entity is still not clarified.

Childhood disintegrative disorder, previously known as Heller's disintegrative psychosis, is behaviorally similar to autism with onset between age 2 and 10 years and a worse prognosis for significant improvement. These children comprise 5 percent of the autistic population and have a history of normal development until the onset of regression. This disorder is sometimes associated with severe epilepsies and progressive neurological disorders.

Rett's syndrome (RS) was first reported in 1966 by Andreas Rett, an Austrian pediatric neurologist. Rett's syndrome occurs almost exclusively in females and has a typically degenerative course. Before the discovery of Rett's syndrome, incidents were mistaken for many other neurologic disorders, especially in females. The specific mutation on the gene related to Rett's syndrome (methyl-CpG binding protein-2 [MECP2]) was identified late in 1999. At least 200 different mutations have been found to be associated with the disease, including missense and truncating mutations. The common BDNF polymorphism may modify disease severity in Rett's syndrome and the severity of the phenotype varies depending on the MECP2 mutation type and locations.

The disorder primarily affects females (though few males have been reported) with prevalence of 1:10,000-15,000 females. The most prominent clinical features include a developmental regression and arrest with microcephaly and motor changes. Abnormalities in respiration, seizures, growth failure, and gastrointestinal disturbances occur. Insidious loss of functional hand use followed by stereotyped hand wringing, and hand-to-mouth movements are pathognomic of the disorder.

A very important aspect of autism is the uneven ability across cognitive skills. The abilities of autistic children may vary from profound mental impairment to superior skills, but even the superior overall ability is associated with areas of lesser competence. In some autistic children the unevenness is so marked that truly exceptional talent may coexist with overall mental incompetence, the so-called savant syndrome. Exceptional ability for music, drawing, calculation, rote memory, visual-spatial abilities or other skills spawns untaught musical geniuses and artists, calendar calculators, and puzzle solvers.¹¹ The magnitude of impairment in autism is age-specific, with the most

profound disturbance in early preschool years and a gradual, though not total, improvement in function over time. While subtle features may be present in the first year of life, the diagnosis should occur between 2 and 3 years of age, but is often delayed.

The core defect in language involves social communication. All children have impairment in pragmatic features, including poor eye contact, voice modulation, problems understanding body meaning, poor use of gestures, and immediate or delayed echolalia.

Play in autism shows impairment in imagination and pretend play. It can have stereotypic features like absent copying, oral exploration or repetitive stereotypic play without vocalization. All children with autism have restricted activities and interests. These include repetitive actions as opening and closing doors and playing with light switches, water; motor stereotypes such as finger flicking, hopping, self spinning, clapping, rocking, etc. Obsessive routine like lining objects and preserving sameness, and a fascination in mechanical or cognitive themes (cars, dinosaurs, trains, numbers, letters, books, etc.) are usual. Most children have a significant resistance to change in routine.

Suspecting ASD in Infancy

It is clear that many parents are seriously concerned about the child's development in the first year of life, and almost 90 percent are very concerned by age 2 years. Common concerns include observations of social deviance or oddity, worries that the child may be deaf, and that the child's language fails to progress.

Clinical Picture

When autism becomes manifest in infancy, parents may complain that the baby is irritable, sleeps poorly, has to be walked by the hour because of screaming, resists being cuddled by arching his back, or that the baby is "too good", lying contentedly in the crib looking at his hands or at a mobile, does not insist on being picked up, and will go to anyone without evincing stranger anxiety.

Motor Skills

Gross motor development, such as sitting and crawling, is often quite normal, with the notable exception of children with overt brain pathology, notably of the girls who will later be diagnosed as having Rett's syndrome who fail to use their hands to grab a toy or feed themselves a cookie and who will be severely delayed or unable to walk.

Communication Skills

Most autistic infants have defective nonverbal communication skills (pragmatics), such as infrequent regarding of parents' face and reciprocal cooing, and lack of pointing or shaking the head "No".

Differentiating between Autism Spectrum Disorders and Other Developmental Disabilities

Children with ASD may have some warning signs similar to those in developmental disorders (DDs)/developmental language disorders (DLDs). However, some impairment may be more typical of those seen in children with ASD.¹² Most striking is the significantly more prominent and consistent impairment in social interaction skills, especially joint attention skills, in children with ASD:

- The ASD group is more impaired on other behaviors, such as imitation, facial expressions, eye contact, and sensory responses
- Young children with ASD are likely to be delayed in using words and their vocalizations are likely to lack consonants and to have unusual prosody
- They are likely not to respond to their name or to instructions even with contextual cues
- They are likely to be delayed in using objects conventionally in play and also are likely to display repetitive movements with their body or objects
- Furthermore, young children with ASD are very likely to be delayed in sharing attention with eye gaze, sharing affect, and drawing others attention to objects or events of interest
- They are very likely to lack the indicating gestures of pointing and showing and lack the coordination of gestures with eye gaze, facial expression, or vocalizations.

Mirror Neuron Systems

A new area of interest in autism research is the role of “mirror neurons” in the sensorimotor cortex, which are activated during the performance of motor acts and while watching others perform them. Discovered in primates, mirror neurons play a critical role in learning by imitation and in understanding similarities between oneself and others, and thus participating in the development of social cognition.¹³ The dysfunction of mirror neurons in imitation skills and empathy may play a significant role in the development of autism, but more research data to support this hypothesis are needed.

DIAGNOSIS AND WORK-UP OF AUTISTIC SPECTRUM DISORDERS

No single sign, symptom, clinical feature, associated handicap, or diagnosis suffices for a diagnosis of autism or invalidates it, and no individual presents all the impairments listed. At the present time no biological marker or simple laboratory test or procedure exists for the diagnosis of autism and related conditions except Rett's syndrome and syndromic ASD. Clinicians must, accordingly, rely on their clinical judgment, aided by guides to diagnosis such as DSM-IV and ICD-10 as well as by the results of various assessment instruments, rating scales or check lists. The latter instruments do

NOT substitute for the diagnosis by an experienced clinician. Recognizing the central importance of early detection and diagnosis, the American Academy of Pediatrics¹⁴ has recently recommended universal screening for ASD at both 18 and 24 months of age. Children identified as being at increased risk of ASD could then benefit from streamlining of subsequent referrals, and initiation of interventions targeted at areas of concern (e.g. development of communication skills). However, to achieve the primary goal of earlier diagnosis, screening for ASD must be followed by timely access to appropriate diagnostic assessment.

- Detailed history should be aimed at determining developmental milestones, developmental regression at any age, identifying any encephalopathic events, history of attention deficit disorder, seizure disorder, depression, mania, troublesome behaviors such as irritability, self-injury, sleep or eating disturbances, and pica for possible lead exposure
- Formal audiologic evaluation: All children with developmental delays, especially those with delays in social and language development, should undergo a formal audiologic hearing evaluation
- *Psychological/communication assessments*
 - Verbal and nonverbal skills must be assessed independently
 - Assessment of social-adaptive behaviors
 - Communication (not just speech) evaluation
 - Nature of social relatedness
 - Behavioral features
 - Play skills
 - Family/living conditions.
- *Medical evaluation:* Clinical examination
- *Metabolic Testing:*

The percentage of children with autism who prove to have an identifiable metabolic disorder is probably less than 5 percent. Metabolic testing or consultation is indicated by a history of lethargy, cyclic vomiting, early seizures, dysmorphic or coarse features, mental retardation or if mental retardation cannot be excluded, questionable newborn screening
- Genetic screening if dysmorphism, family history
- MRI/CT if indicated; EEG.

Tests of Unproven Value

There is inadequate evidence to support routine clinical testing of individuals with autism for hair analysis for trace elements, celiac antibodies, allergy testing (in particular food allergies for gluten, casein, *Candida* and other molds), immunological or neurochemical abnormalities, micronutrients such as vitamin levels, intestinal permeability studies, stool analysis, urinary peptides, mitochondrial disorders (including lactate and pyruvate), thyroid function tests, or erythrocyte glutathione peroxidase studies.¹⁵

Autistic Spectrum Disorders (ASDs) and Epilepsy

The association between autism and epilepsy is now well accepted. Numerous investigators have documented that there is an increased frequency of seizures in ASD. The range of seizure frequency has varied in the literature from a low of 7 percent to a high of 42 percent but the most recent studies suggest that about one-third of children on the autistic spectrum develop epilepsy. There appears to be a two peak distribution to seizures in ASD. One peak occurs in infancy prior to age 5 years and the other occurs in adolescence after age 10 years. Clinical epilepsy develops by adolescence in more than a third of children; its risk is tied to the severity of the underlying brain dysfunction.

Asperger's Syndrome

Autism without mental retardation or delayed language development. There are no specific studies on risk of epilepsy but extrapolation from the studies on risk factors for autism suggests that the likelihood for developing epilepsy is 5 to 10 percent in early childhood.

PDD-NOS

The risk of epilepsy is probably linked to the severity of the underlying brain dysfunction.

Child Disintegrative Disorder

Severe autism acquired between ages 2 and 10 years after entirely normal early development of language, sociability, and cognition. The risk of epilepsy may be as high as 70 percent.

Rett's Syndrome

Specific X-linked genetic deficit strongly associated with mutations of the *MeCP2* gene. It affects postnatal brain growth, resulting in severe mental retardation, motor deficits, and other features. The risk of epilepsy is more than 90 percent.

Management of ASD

Management of these children involves a multidisciplinary team comprising a pediatric neurologist, speech and language therapist, psychologist, occupational therapist, special educator and a social worker. The mainstay of intervention in autism is management of the environment—the physical environment, the people, and events. Individuals with autism are unable or slow to process information and are easily overwhelmed by the environment. They function best when the environment is highly structured and supervised, which means that the world is simplified, interactions are simple and limited, events and people are predictable, and known rules govern actions.

Table 2: Comorbid disorders in autism

<i>Medication—Responsive Problems</i>	<i>Autism—Associated Problems</i>
<ul style="list-style-type: none"> • Attention deficit hyperactivity disorder • Aggression/tantrums • Self-injurious behavior • Anxiety • Obsessive compulsive disorder • Affective disorders • Tic disorder • Sleep disturbance • Epilepsy 	<ul style="list-style-type: none"> • Eating disturbances • Accidental injury • Sleep disturbance • Tantrums • Stimulus hypersensitivity • Dyspraxia • Masturbation • Cognitive impairment • Learning disability

Pharmacological Intervention

There is no cure for autism. The role of medications in autism is to treat the co morbid disorders present (Table 2). The goal of pharmacological therapy is to make the child amenable for the most important therapy – “intensive education”.

Early Childhood Intervention Programs

A number of programs have reported substantial improvement in outcome in children participating in preschool programs that involve 15-40 hours of school-based intervention. Each of these programs focus on training 5 basic skills:

- Ability to attend people and to cooperate with teaching exercises
- Ability to imitate others both verbal imitation and motor imitation
- Ability to comprehend and use language
- Ability to play appropriately with toys
- Ability to socially interact with others.

The teaching should be done in highly structured teaching environment with a high staff to student ratio.

Prognosis

Approximately 50 percent of all autistics function in the retarded range throughout life. Initial cognitive scores are highly predictive. Children with seizures and other indications of organic brain dysfunction tend to be the most retarded, undeveloped, and ultimately impaired. The second group of 25 percent contains children whose motor development is relatively normal and who develop communicative language by 5 years. Children in this group become extremely shy, introverted, and passive in adolescence. They need continued supervision in living situations, but can often function in support employment. The third group of 25 percent has normal intelligence, are able to live and work independently. These persons, however, continue to show personality, social and cognitive impairment.

Approach to a Patient with Delay in Language Development

Monica Juneja, Rahul Jain

INTRODUCTION

Delayed language development is one of the common problems with which children are referred to a pediatrician. Some children with language delays are also identified during screening in well baby clinics. Studies have shown that in pre-school children aged 2 to 4.5 years, the prevalence of language delay ranges from 2.27 percent to 19 percent.¹ Boys are affected much more commonly than girls.¹ Many children mainly those with developmental language disorders outgrow this condition, but in 40 to 60 percent of children with language delays, the problem persists if left untreated.²

Language typically has four components, any of which may be affected in children with language disorders:³

- *Semantics*: Meaning of words, phrases or sentences
- *Syntax*: Rules of grammar, which determine how words are combined to form meaningful sentences
- *Phonology*: The rules for combining sounds of language
- *Pragmatics*: The rules for the social use of language

Language can also be divided into receptive and expressive language. Receptive language refers to the child's ability to understand the nonverbal and verbal communication, while expressive language refers to the child's ability to formulate and express an idea. It is important to understand that speech, which only refers to the production of sound for the act of communication, is not synonymous with language e.g. sign language is also a type of language.³

Language delay can be a manifestation of many disorders, the common ones being hearing impairment, mental retardation, autism and developmental language disorder.³ Before going on to the details of these disorders it is important to know common language milestones (Table 1).⁴

Table 1: Important language milestones
(till 5 years of age)

<i>Receptive language</i>	<i>Expressive language</i>
<ul style="list-style-type: none"> • Recognizes own name 7 months • Response to 'No'-8 months • Understands some words or phrases-10 months • Follow simple one step command with gestures-1 year • Points 2-3 body parts-18 months • Follow simple one step command without gestures-2 years • Follows 2 step command-2 years • Obeys 2 prepositions-3 years • Listen to a short story and answer simple questions about it-4 years • Obeys 4 prepositions-4 years • Follows 3-4 step commands-5 years 	<ul style="list-style-type: none"> • Monosyllables-6 months • Combines syllables-8 months • First word with meaning-12 months • Vocabulary of 8-10 words-18 months • Vocabulary of around 50 words, two-word phrases -2 years • Uses pronouns-3 years • Three-word combinations-3 years • Knows his name and sex-3 years • Uses past tense-4 years • Four word sentences-4 years • Asks questions, converses, and tells stories-4 years • Five word sentences, uses future tense-5 years

CAUSES OF LANGUAGE DELAY

Hearing Impairment

Speech being a learned behavior, hearing impairment at an early stage of development severely affects its

development. Contrary to the popular belief, children with mild hearing loss (15-30 db HL) also have mild language delay miss voiceless consonants. Children with moderate hearing loss (31-50 db HL) cannot hear some speech sounds and hear others inaccurately, commonly missing unstressed words such as prepositions and relational words. Their language delay is associated with confusion related to word meanings and grammatical rules. They have commonly omissions of articles, conjunctions and prepositions. Language, on the other hand, will not develop in children with severe and profound hearing loss, without any intervention.⁵

Hearing loss can be conductive or sensorineural. Sensorineural hearing loss is typically more severe and affects higher frequencies. The common causes of sensorineural hearing loss in children are bilirubin induced neurological damage, bacterial meningitis, perinatal asphyxia, intrauterine infections, ototoxic drugs, and congenital syndromes.⁶

Global Developmental Delay/Mental Retardation

This is the most common cause of language delay, accounting for more than half of the cases. Commonly, there is delayed acquisition of milestones in all the domains of development; however, the language development is usually more severely affected (as compared to the motor development). The delay in language acquisition is global with poor comprehension, impaired gesture use and delay in expressive language, all being commensurate with the cognitive development. Presence of co-morbid hearing impairment may be responsible for disproportionate language delay in some of these patients.

Pervasive Developmental Disorders (PDD)

Impairment in communication is one of the core deficits in PDD. Failure to acquire language at the expected age is the most frequent presenting complaint for preschool autistic children. Approximately, 50 percent of children with autism never develop any speech and some children with PDD show language regression. Language delay however is not a feature of Asperger's disorder.^{7,8}

Children with autism manifest global deficits in language acquisition; however, these deficits are disproportionately more than their cognitive level. These children may poorly understand what is said to them, in fact, this is the only condition where expressive speech may sometimes be more than receptive speech. Children with autism are doubly handicapped as they not only have delayed speech but also have very poor nonverbal communication skills. Thus, they commonly have severe temper tantrums as they are unable to communicate their needs by any means. They may also have atypical gestures like immature pointing and 'handover hand pointing' (using their parents or any other adult's hand to point for objects).^{7,8}

Language acquisition is not only delayed in these children, it may also be deviant. Many verbal autistic children may exhibit immediate and/ or delayed repetition of words or phrases regardless of meaning (echolalia). Some of them also have pronominal reversal (the child refers to himself as 'you' or 'by name', rather than 'I' or 'me'), much beyond 2 to 3 years of age. Some children may speak in a sing-song or monotonous voice.^{7,8}

In addition, other pointers towards autism may be present. They have impairment in social interaction manifesting as poor eye contact, impaired interaction with peers, social aloofness and poor emotional response. These children also have repetitive behaviors in form of repetitive body movements like hand flapping, running in circles, etc. They may also have very unusual interests.^{7,8}

Communication Disorders

The Diagnostic and Statistical Manual of Mental Disorders, 4th edition (DSM-IV) has included language and speech disorders under communication disorders and recognizes five diagnostic categories: (1) expressive, language disorder, (2) mixed receptive-expressive language disorder, (3) phonological disorders, (4) stuttering and communication disorders, (5) not otherwise specified.⁹ Out of these only expressive language disorders, mixed receptive-expressive language disorder and phonological disorders present with speech delay.^{9,10}

Language Disorders

These are behaviorally defined conditions in which there is a delay or abnormality in expressive or receptive language skills in the absence of global cognitive disability, PDDs, hearing loss, environmental deprivation, emotional disturbances, or identifiable neurological disorders.¹¹

Expressive Language Disorders

These children have age-appropriate language comprehension and nonverbal cognition, with delayed expressive language. They have limited vocabulary and have difficulty learning new words. They use short sentences with simplified grammatical structures. In general, these children acquire speech but at a much slower pace than their peers, the speech resembling that of a much younger child.^{9,10}

Fifty to eighty percent of these children outgrow their language difficulties during their preschool years and in these children there is very little risk of learning and behavioral problems later in life. However, when this disorder persists in to early school age years, the expressive language growth continues to lag behind, limiting communication in interpersonal and academic situations. They may also develop other problems like reading and spelling difficulties and Attention Deficit Disorders in early school years. Most of these children also acquire

normal language abilities by late adolescence, although subtle deficits may persist.⁹⁻¹⁴

Mixed Receptive-Expressive Language Disorder

There is impairment in both receptive and expressive languages which are substantially below the child's nonverbal cognitive abilities. Mostly the receptive and expressive languages are proportionately delayed. In addition to the features seen in expressive language disorder, these children have difficulty in understanding words and sentences. Thus, a 2-year-old child may understand names of familiar people or objects, but there may be limited understanding of simple one step commands. In mild cases, there may be difficulties only in particular type of words (e.g. spatial words like "behind", "next to" or "under") or statements (e.g., complex "if-then" sentences).^{9,10}

Mixed receptive-expressive language disorder is usually detected before age 4 years, however, milder cases may not be recognized till the child reaches elementary school. Some children eventually acquire language skills within the normal range but their overall prognosis is poorer than that of expressive language disorder. Two-third of school age children with persistent mixed receptive-expressive language disorders have psychiatric comorbidity, Attention Deficit Hyperactivity Disorder being the most common.⁹⁻¹⁴

Phonological Disorders

Phonological disorders are characterized by failure to use speech sounds that are expected for the age and dialect. This may involve omission (e.g. saying *nana* for *banana*), substitution (e.g. saying *tap* for *cup*) or distortion of certain sounds, lisping being the commonest phonological disorder. There may also be problems with organization of sounds in an individual word (e.g. saying *pakda* for *kapda*). In severe cases the speech may be delayed in onset and unintelligible. The phonological disorders include both disorders with no known cause and disorders arising from hearing impairment, structural abnormalities (e.g. cleft lip and palate) and neurological conditions (like cerebral palsy).^{9,10}

Speech Apraxia

This is a type of phonological disorder which results from impairment in planning and executing speech movements despite normal range of movement and muscle strength in oro-motor system. The apraxia may be limited to speech or be generalized, involving other activities. The child's effort to imitate a sound seems labored and ineffective and the speech is often confined to short utterances. The hallmark of speech apraxia is dysfluency, i.e. at times the child speaks a word clearly, but cannot repeat the same on command. These children also have feeding

problems, starting early in life and have excessive drooling. Boys are more commonly affected, and family history is often present.^{6,10}

Dysarthria

This is a phonological disorder associated with neurological conditions like cerebral palsy, neuromuscular disorders, etc. manifesting as slow, labored and slurred speech.^{6,10}

Elective Mutism

Elective mutism is a psychological disorder in which a child does not speak in school, public situations or with strangers, but will speak when he/ she is alone or with his/ her friends or parents. These children also manifest other features of poor adjustment like social withdrawal, excessive shyness and overdependence on parents.⁶

Psychosocial Deprivation

Psychosocial deprivation in form of inadequate exposure to language and child neglect, can adversely affect the speech development.⁶

APPROACH TO A CHILD WITH LANGUAGE DELAY

Most of the children with language delay present at 18 to 36 months of age. Screening and surveillance for language delay helps in picking up of these children at early age. A child should have a complete evaluation if he is having any of the following red flag signs:

- Not babbling by the age of 12 months
- No pointing by 12 months
- No words by 16 months
- Not understanding simple commands by 18 months
- No two-word meaningful phrases (without imitating or repeating) by 24 months
- Not making 2 to 3 word sentences by 3 years of age
- Any loss of speech.

In such a child, the first step is to take a detailed history of language development, including the comprehension level of the child and use of gestures. Any regression in language should be noted. This information can then be used to ascertain the language age of the child. A detailed developmental history in other domains is also obtained, to look for global deficits. The nonverbal cognitive abilities of the child help in differentiating language disorders and mental retardation (Table 2). The history of the child's response to being called and response to everyday noises including soft sounds should be obtained to evaluate his/her hearing.^{6,11,15,16}

If the child has poor language comprehension, impaired gesture use, language regression or differential responses to noises, the parents should also be interviewed in detail about the social interaction of the child including his play and other characteristic features of autism.

Table 2: Nonverbal cognitive abilities

- Object permanence (searches for hidden object)—12 months
- Cooperates with adult in simple household tasks—2 years
- Imitates vertical and circular strokes—2 years
- Enjoys simple make-believe play—3 years
- Copies circle—3 years
- Draw a man with 2 parts—3 years
- Matches primary colors—3 years
- Copies cross—4 years
- Draw a man with 3 parts—4 years
- Copies triangle—5 years
- Draw a man with 6 parts—5 years

An inquiry should be made for situational difficulties in speech, especially in children who are otherwise normal, to rule out elective mutism. Difficulties in feeding, excessive drooling and other neurological deficits are pointers towards phonological disorders.

Other pertinent histories are psychosocial history specially focusing on language stimulation at home and family history of speech delay.

Also, history should be taken for identifying etiology of mental retardation and hearing impairment including history of maternal illnesses during pregnancy, perinatal asphyxia or trauma, bilirubin induced neurological damage, prematurity, birth weight, past history of head trauma or infections of the nervous system, and use of ototoxic drugs.

It is important to remember that tongue-tie and bilingualism do not cause language delay.

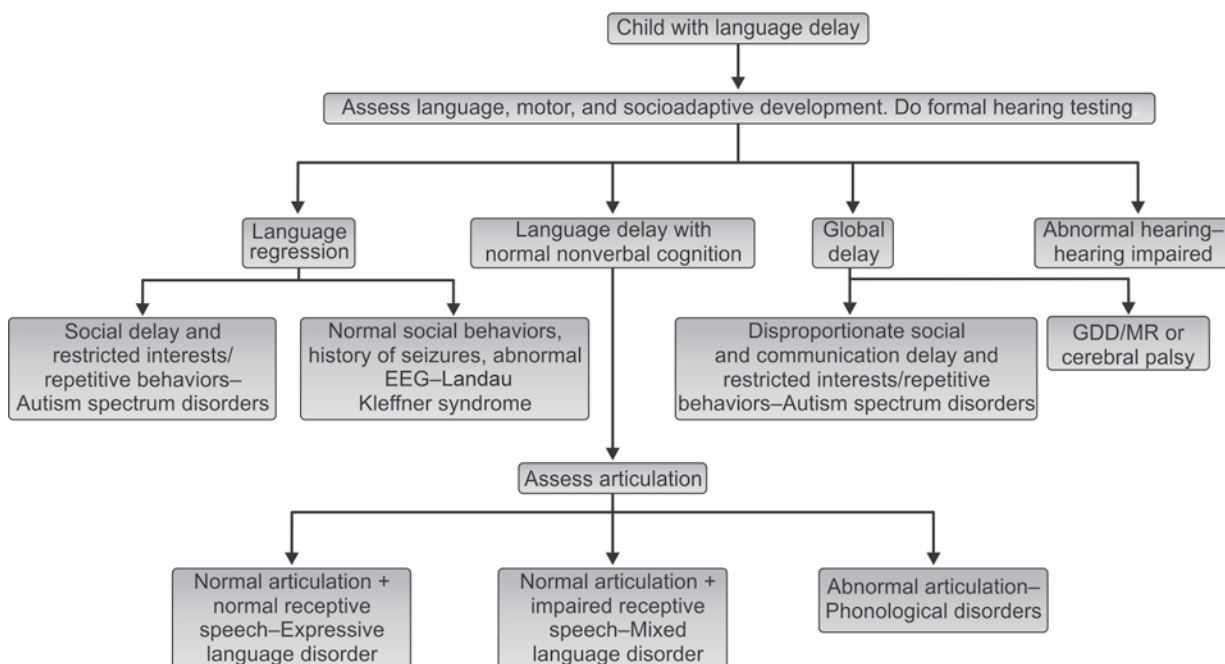

The physical examination should include a thorough examination of ear, nose and throat especially for any cleft lip or palate, and assessment for dysmorphism. A complete neurological assessment should be done including motor system examination, and hearing assessment. It is however important to remember that behavioral hearing evaluation is not reliable.

A physician should also spend some time observing the interaction of the child with his parents and observing his behavior. It gives a good clue of the child's language comprehension, use of gestures and cognitive ability.

Diagnostic Evaluation

All children with speech delay should have formal hearing evaluation. Hearing screen should be done using Otoacoustic Emissions (OAE) or screening BERA test. The advantage of screening BERA is that it evaluates hearing till brainstem level, while OAE evaluates till cochlear level only. Any child who fails on screen should have detailed evaluation by Full BERA or Audiometric Steady State Response. The gold standard for hearing evaluation is Pure Tone Audiometry, however, it can be done reliably only in an older and cooperative child.

All children have to be evaluated by a speech-language pathologist, who will do detailed speech and language assessment using formal test like Receptive-expressive Emergent Language Scale (REEL) or Linguistic Profile Test (LPT), besides hearing evaluation. He would also evaluate for specific phonological disorders.

Flow chart 1: Approach to a child with language delay

All children with language delay should preferably also have an assessment of their development/intelligence quotient, using standardized tools like Developmental Assessment Scale for Indian Infants (DASII), Binet Kulshrestha Test (BKT), Malin's Intelligence Scale for Indian Children (MISIC), etc. by a clinical psychologist. Special non-verbal tools like Raven's progressive matrices and Leiter-R scale can be used for assessing children with hearing impairment.

In a child with language regression or variation in the severity of language disorder, electroencephalography should be done to rule out subclinical epilepsy or syndromes like Landau-Kleffner syndrome. Other diagnostic evaluations like neuroimaging, chromosomal analysis, etc. should be based on findings on history or physical examination. A simplified algorithm for approaching a child with language delay is provided in Flow chart 1.

Early diagnosis and management are necessary to improve the outcomes in these children. A multidisciplinary team approach involving the pediatrician, speech therapist, audiologist and clinical psychologist is a must in the assessment and treatment of these children. The management plan is individualized with active involvement of parents in the treatment program. Early management of hearing impairment is of utmost importance.

Attention Deficit Hyperactivity Disorders

Roma Kumar

These are children who never sit still. They are always into something or the other but they never prolong in a task. They don't pay attention to what others say. They never think before they act. In school, they are often up and out of their seats in a fraction of a second. They do not do well in school and often lag behind their peers. Such problems are of concern to parents and teachers. The children who exhibit these symptoms of inattention and impulsivity are diagnosed as attention deficit hyperactivity disorder (ADHD) children.

HISTORICAL BACKGROUND OF ATTENTION DEFICIT HYPERACTIVITY DISORDER

The deviance of behavior, which is at present termed 'Attention deficit hyperactivity disorder', has travelled a long road of conceptualization (Barkley, 1996). In the distant past, an English physician called George Still described a group of boys with a defect in moral control 'as inattentive, impulsive, and overactive' lawless and aggressive.

Earlier conceptualizations gave emphasis to the over activity or motor restlessness of these children. Hence the terms 'hyperkinesis' and 'hyperkinetic syndrome' were variously applied (Barkley, 1989). At present we use the term 'hyperactivity' to denote the excessive motor activity. Yet several other behavioral problems were recognized as being associated with hyperactivity, they are attention deficit and impulsivity. Gradually, attention deficits took central role and hyperactivity was downgraded in importance. This shift in conceptualization was reflected in DSM-III (1980) classification, which recognized attention deficit disorder with hyperactivity (ADHD) or without hyperactivity. In DSM-III-R (1987), the disorder was relabeled attention deficit hyperactivity disorder (ADHD). The category of attention deficit without hyperactivity was dropped. Children were diagnosed on the basis of displaying eight of fourteen behaviors, which

could be different mixes of inattention, hyperactivity and impulsivity. That is, ADHD was viewed as unidimensional, so that any mix of symptoms met the criteria. Along with the changing criteria, ideas about etiology also shifted and included brain damage, minimal brain damage and to a lesser extent, environmental influences.

CLASSIFICATION AND DIAGNOSIS OF ATTENTION DEFICIT HYPERACTIVITY DISORDERS

Due to the problem in defining the relationship among inattention, hyperactivity, and impulsivity as to whether view them as a part of a single dimension or co-occurring independent dimensions, DSM-IV-TR reconceptualized the disorder.

CLINICAL CHARACTERISTICS OF ATTENTION DEFICIT HYPERACTIVITY DISORDERS

Children with ADHD are often said to exhibit the characteristics, such as in attentiveness, distraction, lack of sustained attention, hyperactivity and impulsivity.

Inattentiveness

Inattention problems are noted in various ways among children with ADHD. The children with ADHD were tested on two other elements of attention: selective attention and sustained attention. 'Selective attention' refers to the ability to attend to relevant environmental stimuli or not to be distracted by irrelevant stimuli. The findings of Leung and Connolly (1996) indicate that the introduction of irrelevant stimuli does distract children with ADHD. For example, Milich and Lorch (1994) found that the boys with ADHD were more distracted from television watching by the presence of toys than the normal boys.

Similarly, 'sustained attention' refers to paying attention to a task over a period of time. The findings of Losier, McGrath and Klein (1996) reveal that the children

Diagnostic Criteria for ADHD

<i>DSM-IV-TR diagnostic criteria for attention deficit hyperactivity disorder</i>	<i>ICD-10 diagnostic criteria for hyperkinetic disorder</i>
<p>A. Either (1) or (2)</p> <p>(1) Six (or more) of the following symptoms of inattention have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level:</p> <ul style="list-style-type: none"> • Inattention <ul style="list-style-type: none"> – Often fails to give close attention to details or makes careless mistakes in school work, work, or other activities. – Often has difficulty sustaining attention in tasks or play activities. – Often does not seem to listen when spoken to directly – Often does not follow through on instructions and fails to finish school-work, chores, or duties in the workplace (not due to oppositional behavior or failure to understand instructions). – Often has difficulty organizing tasks and activities. – Often avoids, dislikes, or is reluctant to engage in tasks that require sustained mental effort (such as school work or homework). – Often loses things necessary for tasks or activities (e.g. toys, school assignments, pencils, books or tools). – It is often easily distracted by extraneous stimuli. – It is often forgetful in daily activities. <p>(2) Six or more of the following symptoms of hyperactivity—impulsivity have persisted for at least six months to a degree that is maladaptive and inconsistent with developmental level:</p> <ul style="list-style-type: none"> • Hyperactivity <ul style="list-style-type: none"> – Often fidgets with hands or feet or squirms in seat. – Often leaves seat in classroom or in other situations in which remaining seat is expected. – Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, may be limited to subjective feelings of restlessness). – Often has difficulty playing or engaging in leisure activities quietly. – It is often “on the go” or often acts as if “driven by motor”. 	<p><i>Note:</i> The research diagnosis of hyperkinetic disorder requires the definite presence of abnormal levels of abnormal levels inattention, hyperactivity, and restlessness that are pervasive across situations and persistent over time and that are not caused by other disorders such as autism or affective disorders.</p> <ul style="list-style-type: none"> • G1. Inattention: At least six of the following symptoms of attention have persisted for at least six months, to a degree that is maladaptive and inconsistent with the developmental level of the child: <ul style="list-style-type: none"> – Often fails to give close attention to details, or makes careless errors in school work, work or other activities. – Often fails to sustain attention in tasks or play activities. – Often appears not to listen to what is being said to him or her. – Often fails to follow through on instructions or to finish school work, chores, or duties in the workplace (not because of oppositional behavior or failure to understand instructions). – It is often impaired in organizing tasks and activities. – It often avoids or strongly dislikes tasks, such as homework, that require sustained mental effort. – It often loses things necessary for certain tasks and activities, such as school assignments, pencils, books, toys or tools. – It is often easily distracted by external stimuli; – It is often forgetful in the course of daily activities. • G2. Hyperactivity: At least three of the following symptoms of hyperactivity have persisted for at least six months, to a degree that is maladaptive and inconsistent with the developmental level of the child: <ul style="list-style-type: none"> – Often fidgets with hands or feet or squirms on seat. – Leaves seat in classroom or in other situations in which remaining seated is expected. – Often runs about or climbs excessively in situations in which it is inappropriate (in adolescents or adults, only feelings of restlessness may be present). – Is often unduly noisy in playing or has difficulty in engaging quietly in leisure activities. – Exhibits a persistent pattern of excessive motor activity that is not substantially modified by social context or demands. • G3. Impulsivity: At least one of the following symptoms of impulsivity has persisted for at least six months, to a degree that is maladaptive and inconsistent with the developmental level of the child:

DSM-IV-TR diagnostic criteria for attention deficit hyperactivity disorder	ICD-10 diagnostic criteria for hyperkinetic disorder
<ul style="list-style-type: none"> – It often talks excessively • Impulsivity <ul style="list-style-type: none"> – Often blurts out answers before questions have been completed – Often has difficulty awaiting turn – Often interrupts or intrudes on others (e.g., butts into conversations or games) <p>B. Some hyperactive-impulsive or inattentive symptoms that caused impairment were present before age seven years.</p> <p>C. Some impairment from the symptoms is present in two or more settings (e.g. at school [or work] and at home).</p> <p>D. There must be clear evidence of clinically significant impairment in social, academic, or occupational functioning.</p> <p>E. The symptoms do not occur exclusively during the course of a pervasive developmental disorder(PDD), schizophrenia, or other psychotic disorder and are not better accounted for by another mental disorder (e.g. mood disorder, anxiety disorder, dissociative disorders, or a personality disorder).</p>	<ul style="list-style-type: none"> – Often blurts out answers before questions have been completed. – Often fails to wait in lines or await turns in games or group situations. – Often interrupts or intrudes on others (e.g. butts into others conversations or games). – Often talks excessively without appropriate response to social constraints. • G4. Onset of the disorder is no later than the age of seven years. • G5. Pervasiveness: The criteria should be met for more than a single situation, e.g. the combination of inattention and hyperactivity should be present both at home and at school, or at both school and another setting where children are observed, such as a clinic. (Evidence for cross-situationality will ordinarily require information from more than one source; parental reports about classroom behavior, for instance, are unlikely to be sufficient). • G6. The symptoms in G1 and G3 cause clinically significant distress or impairment in social, academic, or occupational functioning. • G7. The disorder does not meet the criteria for pervasive developmental disorders, manic episode, depressive episode, or anxiety disorders.
<p>Code based on type:</p> <ul style="list-style-type: none"> • 314.01 Attention-Deficit Hyperactivity Disorder, Combined Type: If both criteria A1 and A2 are met for the past 6 months. • 314.00 Attention-Deficit Hyperactivity Disorder, Predominantly Inattentive Type: If criterion A1 is met but criterion A2 is not met for the past 6 months. • 314.01 Attention-Deficit Hyperactivity Disorder, Predominantly Hyperactive-Impulsive Type: If criterion A2 is met but criterion A1 is not met for the past 6 months. 	<p>Comments</p> <ul style="list-style-type: none"> – Many authorities also recognize conditions that are sub-threshold for hyperkinetic disorder. Children who meet criteria in other ways but do not show abnormalities of hyperactivity/impulsiveness, may be recognized as showing attention deficit; conversely, children who fall short of criteria for attention problems but meet criteria in other respects may be recognized as showing activity disorder. In the same way, children who meet criteria for only one situation (e.g. only the home or only the classroom) may be regarded as showing a home-specific or classroom-specific disorder. These conditions are not yet included in the main classification because of insufficient empirical predictive validation, and because many children with sub-threshold disorders show other syndromes (such as oppositional defiant disorder [ODD]) and should be classified in the appropriate category. – Disturbance of activity and attention. – The general criteria for hyperkinetic disorder must be met, but not those for conduct disorders. – Hyperkinetic conduct disorder. – The general criteria for both hyperkinetic disorder and conduct disorders must be met.

DSM-IV-TR diagnostic criteria for attention deficit hyperactivity disorder	ICD-10 diagnostic criteria for hyperkinetic disorder
Coding note: For individuals (especially adolescents and adults) who currently have symptoms that no longer meet full criteria, "In Partial Remission" should be specified.	<ul style="list-style-type: none"> – Other hyperkinetic disorder – Hyperkinetic disorder, unspecified. – This residual category is not recommended and should be used only when there is a lack of differentiation between disturbance of activity and attention and hyperkinetic conduct disorder but the overall criteria for hyperkinetic disorders are fulfilled.

with attention deficit hyperactivity disorder (ADHD) are deficient in sustained attention. When the length of the given task increases, a deficit in sustained attention would lead to a worsening of performance.

Hyperactivity

Children with ADHD are described as always on the run, restless, fidgety and unable to sit still. They squirm, wiggle, tap their fingers and elbow (Greenhill, 1991). Very often, they have minor mishaps, such as spilling drinks, knocking over objects as well as more serious accidents that result in bodily harm. They are excessively energetic, haphazard, disorganized and lacking in goals. They also appear to have difficulty in regulating their actions according to the wishes of others or to the demands of the particular situation. The devices, such as actometers and pedometers are helpful in measuring movement can be used to demonstrating the excessive movement of children with ADHD.

Impulsivity

Impulsivity refers to the deficiency in inhibiting behavior, which appears as 'acting without thinking'. The children with ADHD may jump in and try to solve a problem before figuring out the first step, heedlessly engage in dangerous behaviors, and take shortcuts while performing a task. Games that require patience or restraint are not well negotiated and they may also interrupt others or blurt out socially inappropriate or hurtful verbalizations. In short, they are unable to hold back, inhibit and control behavior and their behaviors often lead others to judge them as careless, irresponsible, immature, lazy or rude. The findings of Oosterlaan, Logan and Sergeant (1998) reveal that inhibition of motor responses is an important characteristic of children with ADHD. Although, the children diagnosed as ADHD are heterogeneous with regard to symptoms, the most frequently seen type is combination of inattention, hyperactivity and impulsiveness.

TYPES OF ATTENTION DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD) has various forms, in which the three elements hyperactivity, impulsivity and attention deficit play a part.

- *Attention deficit hyperactivity disorder (ADHD), combination form hyperactivity-impulsivity-attention deficit:* Most children with ADHD fall under the combination form category and suffer from the three characteristics together. Children with ADHD combination form have a chaotic behavior style. They are extremely active, impulsive and have difficulty with concentrating. Their restlessness is uncontrolled. Transferring information into actions does not run correctly. Absorbing and processing signals and subsequently taking a decision is still apparent with these children in general. These children have learning difficulties and fear of failure, and as the requirements become higher, the problems increase. The criteria for the diagnosis ADHD combination form are, according to the DSM-IV, having at least six symptoms of attention deficit and at least six symptoms of hyperactivity-impulsivity.
- *Attention deficit hyperactivity disorder (ADHD), attention deficit:* With ADHD attention deficit, also called attention deficit disorder (ADD), the child does not come across as being active and chaotic. This disorder is generally only visible with tasks that require concentration. The concentration of the child with ADHD deviates from the concentration disorder of a child with limited intellectual powers. The child with ADHD, the concentration problems are there from the beginning of a task and are an issue continuously. The child will therefore, come across as being active. With a child with limited intellectual powers the concentration runs out, as it were, and the child is subsequently more likely to be tired than active. For diagnosis ADHD attention deficit, there have to be at least six symptoms of attention deficit and fewer than six of hyperactivity-impulsivity.
- *Attention deficit hyperactivity disorder (ADHD), hyperactivity-impulsivity:* In the case of the form ADHD hyperactivity-impulsivity the child is able to concentrate on tasks. It is however, extremely active and chaotic. In structured situations, where concentration is necessary, the child is often calm and the hyperactivity and impulsivity are less obvious. This often applies to the school situation. In that case teachers do not recognize the child's behavior that the parents talk about. It applies to the diagnosis ADHD hyperactivity-impulsivity that at least

six symptoms of hyperactivity-impulsivity are present and fewer than six symptoms of attention deficit.

ETIOLOGICAL THEORIES

Many theories have been developed to account for ADHD (Tannock, 1998), some of which are summarized below. These theories fall into three main categories. First, there are those that focus largely on the role of biological factors in the etiology of ADHD. Second, there are intrapsychic theories, which attempt to explain the syndrome of inattention, over-activity and impulsivity through reference to a central underlying deficit. Third, there are those that deal with the role of psychosocial factors in the development of the condition.

BIOLOGICAL THEORIES

Genetic Hypothesis

Genetic hypothesis suggest that ADHD symptomatology or a pre-disposition to hyperactivity is inherited by children who develop the condition. In support of this hypothesis, twin, adoption and family studies shows that rates of ADHD are higher in the biological relatives of children with ADHD than those without the disorder (Barkley, 2003; Thapar and Scourfield, 2002). Twin studies show that the heritability coefficient for ADHD is at least.⁸ (which is higher than that for intelligence, typically estimated at.⁵ to.);⁷ 20 percent of the variance in the ADHD symptomatology. Molecular genetic studies have found an association between ADHD and the dopamine transporter gene and dopamine receptor gene. The search for these genes was informed by evidence for dysregulation of the dopamine system in the prefrontal region of the brain, associated with executive function, in children with ADHD.

Neurotransmitter Dysregulation Hypothesis

The neurotransmitter dysregulation hypothesis attributes the symptoms of ADHD to abnormalities in neurotransmitter functioning in centers which sub serve behavioral activation and executive functioning. There is growing evidence to show that a dysregulation of the dopamine and noradrenaline systems in the prefrontal cortex and basal ganglia occur in ADHD (Barkley, 2003; Schachar and Tannock, 2002).

Hypoarousal Hypothesis

The hypoarousal hypothesis explains hyperactivity and inattention as a failure to be sufficiently aroused by signal stimuli to attend to them and regulate activity levels. Psychophysiological studies indicate that ADHD children show reduced psychophysiological responsiveness [as assessed by electroencephalography (EEG) and heart rate) to novel stimuli with signal value (Barkley, 2003)].

INTRAPSYCHIC THEORIES

Many intrapsychic theories have been developed to explain the patterns of symptomatology in ADHD. These are:

Inattention Hypothesis

The inattention hypothesis argues that problems with sustaining attention on a single task and screening out other distracting stimuli is the core difficulty that under-pins the other symptoms of impulsivity and overactivity in ADHD (e.g. Douglas, 1983). That is, youngsters with ADHD at the outset of a task requiring attention will perform at a level equivalent to normal children but, over time. They will show more errors, which are directly attributable to the inability to sustain attention. This problem with sustaining attention leads them to change the focus of the attention frequently and this is manifested at a behavioral level as excessive impulsivity and overactivity.

Hyperactivity Hypothesis

The hyperactivity hypothesis argues that a problem with inhibiting motor activity is the core deficit that under pins the ADHD syndrome and can account for inattention and impulsivity (e.g. Quay, 1997; Schachar, 1997). A large body of evidence shows that hyperactivity is a unique symptom to children with ADHD compared to children with other psychological problems, and that hyperactivity is a construct correlates with many academic indices of attention problems (Barkley, 2003).

Impulsivity Hypothesis

This hypothesis argues that a core problem in inhibiting cognitive and behavioral responses to specific stimuli leads to poor performance on tasks apparently requiring good attentional abilities and also to tasks requiring planning and careful regulation of behavior. Thus, the central problems in ADHD, according to this hypothesis, are with cognitive and behavioral impulsivity (Nigg, 2001).

According to this theory, with academic task apparently requiring high levels of sustained attention, children with ADHD have problems using systematic cognitive problem-solving strategies because they are cognitively impulsive. Also, in both academic and social situations, children with ADHD engage in careless work practices in school and in socially inappropriate behavior with peers, parents and teachers because they are behaviorally impulsive (Barkley, 2003).

Executive Function Hypothesis (Flow Chart 1)

Russell Barkley (2003) argues that the symptoms of ADHD (impulsivity, over-activity and inattention) reflect a central deficit in the core executive function of behavioral inhibition that is neurodevelopmental (rather than social) in origin. Children with deficits in behavioral inhibition cannot

delay immediate gratification, so reap better rewards later. This core deficit in behavioral inhibition is associated with, and reinforced by secondary deficits in four other executive functions:

- Nonverbal working memory
- Verbal working memory (or internalization of speech)
- Self-regulation of affect, arousal and motivation
- Verbal and behavioral creativity and fluency (or internalization of play). With poor verbal and nonverbal working memory, ADHD children cannot hold a picture of events of the mind, or obey a set of self-directed instructions and so delay gratification or sustain planned sequences of goal-directed behavior. With poor self-regulation of affect, motivation and arousal, ADHD children have difficulty in preventing strong emotional experiences and motives from interfering with planned goal-directed behavior.

With poor internalization of play, ADHD children have difficulty developing, rehearsing and implementing creative plans to achieve novel goals. The four secondary executive function deficits, according to Barkley, reflects failures to internalize and private functions that, in early development, were external features of child's interactions with caregivers. In normal development, the emergence of these four executive functions reflects a shift in the source of control of behavior from external events to mental representations of events, from control by others to control by the self and from immediate to delayed gratification. This complex and elaborate executive function hypothesis has to some degree supplanted earlier simpler psychological theories and is partially supported by a growing body of empirical evidence (Barkley, 2003).

SYSTEM THEORY

System theories have focused largely on the role of the family system or the wider social context in the etiology and maintenance of ADHD. With respect to family problems, high stress and low support; parent psychological

problems such as depression, aggression or alcohol abuse; exposure to marital discord; over-intrusive parenting and coercive parent-child interactions in childhood and adolescence have all been found to have associations with ADHD (Lange et al. 2005). With respect to the wider social system, the following factors have been found to be associated with ADHD: low socioeconomic status, institutional upbringing and peer relationship problems (Barkley, 2003).

ATTENTION DEFICIT HYPERACTIVITY DISORDER AND CO-OCCURRING DISORDERS

Attention deficit hyperactivity disorder (ADHD) is a highly co-morbid disorder and is often accompanied by another disorder. Approximately 66 percent of elementary school-aged children referred to clinics with ADHD have, at a minimum, one additional diagnosable disorder (Cantwell, 1994). One of the most often occurring co-morbid problems is delayed toilet-training, both encopresis, soiling and enuresis bedwetting. Attention deficit hyperactivity disorder (ADHD) children often show learning disorders which are connected with a disrupted maturation of the central nervous system: dyslexia (reading and writing disorder), mathematics disorder and dysgraphia (writing disorder). These learning disorders occur, just like other maturation disorder, predominantly with boys.

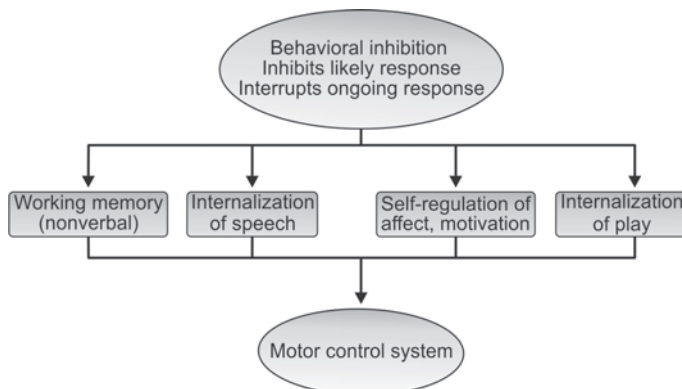

Children with ADHD frequently have difficulties in social interaction. They are frequently reported as non-compliant, oppositional, annoying and argumentative, in short, the behavior diagnosed as oppositional defiant disorder (ODD). Further, ODD may lead to conduct disorder (CD), which involves aggression, deceit and violations of rules. Children with ADHD, with co-occurrence of ODD and CD problems, show greater levels of aggression, lying, cheating and stealing (Jensen, Martin and Cantwell, 1997). Barkley (1998a) also reported that about 25 percent children with ADHD also have anxiety disorders. Along with the disruptions of ADHD, they experience the fears, worries and other internalizing problems of anxiety. The co-occurrence of ADHD and depression was also reported by Biederman et al (1996).

ASSESSMENT OF ATTENTION DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD) is conceptualized as a bio psychosocial disorder and hence assessment of ADHD must be broad based and include various procedures that are capable of evaluating the primary and secondary manifestations of disorder, family functioning and biologically functioning. Moreover, ADHD is situationally specific in nature at times; evaluation should include different settings, such as home and school. The widely used assessment tools for ADHD are interviews, rating scales, direct observation and other procedures.

Flow chart 1: Barkely model of ADHD symptomology

Adopted from: Barkley, RA. ADHD: A handbook by diagnosis and treatment. New York: Guilford Press, 1998

Interviews

In most case of ADHD, parents are the chief source of information. Hence, standard, structured or semi-structured interviews can be used. Information with regard to the child's as well as the family's history, the school, the child's behavioral problems and strengths should be obtained through interviews. Details about the situations identified as troublesome should also be obtained through interviews. Teacher interviews are of much value and the focus of teacher interview should be on learning and academic problems as well as on peer interactions. In addition, information can be obtained about parent-school interaction and co-operation as well as school services.

Rating Scales

Parent and teacher rating scales and checklists are other popular tools assessing ADHD and they provide much information with relatively little time and effort. Rating scales are useful not only to identify ADHD but also its co-occurrence with other disorders. Both broadband and narrow band rating scales are available. The broadband scales are helpful in determining whether the behavior is deviant from the norm and different from behaviors displayed by other diagnostic groups. The narrowband scales are useful in assessing specific aspects of ADHD, such as school behavior. For several of the instruments, both parent and teacher versions are available. There are also self-report versions, which are particularly useful for adolescents.

The Conners parent and teacher scales (Conners et al. 1998a) are widely employed for initial screening. They are easy to use and there is good evidence for their validity (Edolbrock and Rancurello, 1985). Moreover, both scales have been revised recently.

TREATMENT OF ATTENTION DEFICIT HYPERACTIVITY DISORDER

Various treatments have been applied to ADHD. Pharmacological medication and behavioral interventions are the best choice.

- *Pharmacological treatment:* Many pharmacological agents like stimulant, antidepressant and anticonvulsant drugs have been used for ADHD. The most commonly used medications are given below:
 - Most common medication for ADHD
- *Stimulants:* Medications of first choice
 - Ritalin (Methylphenidate)
 - Dexedrine (Dextroamphetamine)
 - Cylert (Pemoline)
 - Adderall (combined Amphetamine and Dextroamphetamine)
- Antidepressants: First alternative choice
 - Tricyclics (e.g. Desipramine, Imipramine)

- Other antidepressants
- Less –Used medication
 - Anticonvulsants
 - Antihypertensives
 - Antipsychotics.

An estimated 75 percent of stimulant medicated children show increased attention and reduced impulsivity and activity level, both in the laboratory and in the structured, natural environments that elicit ADHD behaviors (Whalen and Henker, 1998). Stimulant medications can also reduce co-occurring aggressive, noncompliant, oppositional behaviors (Hinshaw et al. 1989).

- *Behavioral interventions:* Since the pharmacological treatments have short-term success and cause intolerable side effects, behavioral interventions are often recommended to treat ADHD. Behavioral interventions are applied to a wide range of problems.
- *Psychotherapy* works to help people with ADHD to like and accept themselves despite their disorder. It does not address the symptoms or underlying causes of the disorder. In psychotherapy, patients talk with the therapist about upsetting thoughts and feelings, explore self-defeating patterns of behavior, and learn alternative ways to handle their emotions. As they talk, the therapist tries to help them understand how they can change or better cope with their disorder.
- *Behavioral therapy (BT)* helps people develop more effective ways to work on immediate issues. Rather than helping the child understand his or her feelings and actions, it helps directly in changing their thinking and coping and thus may lead to changes in behavior. The support might be practical assistance, like help in organizing tasks or schoolwork or dealing with emotionally charged events. Or the support might be in self-monitoring one's own behavior and giving self-praise or rewards for acting in a desired way such as controlling anger or thinking before acting.
- *Social skills training* can also help children learn new behaviors. In social skills training, the therapist discusses and models appropriate behaviors important in developing and maintaining social relationships, like waiting for a turn, sharing toys, asking for help, or responding to teasing, then gives children a chance to practice. For example, a child might learn to "read" other people's facial expression and tone of voice in order to respond appropriately. Social skills training help the child to develop better ways to play and work with other children.
- *Parenting skills* training, offered by therapists or in special classes, gives parents tools and techniques for managing their child's behavior. One such technique is the use of token or point systems for immediately rewarding good behavior or work. Another is the use of "time-out" or isolation to a chair or bedroom when the child becomes too unruly or out of control.

During time-outs, the child is removed from the agitating situation and sits alone quietly for a short time to calm down. Parents may also be taught to give the child "quality time" each day, in which they share a pleasurable or relaxing activity. During this time together, the parent looks for opportunities to notice and point out what the child does well, and praise his or her strengths and abilities.

This system of rewards and penalties can be an effective way to modify a child's behavior. The parents (or teacher) identify a few desirable behaviors that they want to encourage in the child – such as asking for a toy instead of grabbing it, or completing a simple task. The child is told exactly what is expected in order to earn the reward. The child receives the reward when he performs the desired behavior and a mild penalty when he doesn't. A reward can be small, perhaps a token that can be exchanged for special privileges, but it should be something the child wants and is eager to earn. The penalty might be removal of a token or a brief time-out. Make an effort to find your child being good. The goal, over time, is to help children learn to control their own behavior and to choose the more desired behavior. The technique works well with all children, although children with ADHD may need more frequent rewards.

Idiopathic Mental Backwardness

Chhaya Sambharya Prasad

INTRODUCTION

Idiopathic mental backwardness refers to individuals with low intelligence who show no evidence of gross chromosomal defects or single-gene anomalies. It may also represent the lower end of intelligence quotient (IQ) distribution. Backwardness is defined as one which makes less progress than normal. Mental backwardness means a person with the intellectual capacity that developed at a below average rate during the early developmental years. Several syndromes (such as Downs, Fragile, Rett syndrome, and other well known conditions) can be easily suspected because of their association to specific dysmorphisms, behavioral peculiarities, and multiple congenital abnormalities. However, a consistent percentage of children with genetic mental retardation do not present a recognizable phenotype which is striking of a well-recognizable syndrome. Determining a specific etiologic diagnosis is central to understand the nature of the problem, providing answers to questions regarding prognosis, recurrence risks, directing specific therapies, and achieving meaningful inclusion of individuals with disability into society.

Mental backwardness represents one of the most frequently diagnosed disabling condition in our society, and a lifelong disability characterized by impairment of cognitive and adaptive skills. The etiology is very heterogeneous and, unfortunately, in more than one-half of cases the cause is still unexplained. Anything that damages and interferes with the growth and maturation of the brain can lead to mental backwardness. This might happen before, during or after the birth of the child (including complications of pregnancy/birth, toxics, malnutrition, trauma, infections, under stimulation). Moreover, genetically determined etiology (comprising chromosomal aberrations, single-gene disorders, and

other genetic conditions) account by itself only for 17 to 41 percent of cases, depending of the different techniques of analysis.

MAGNITUDE OF THE PROBLEM

Mental ability is always more likely to be underestimated than overestimated, especially in case of persons from lower socioeconomic groups. India is a vast country with variable social, cultural, geographical and economic background. Communicable diseases and congenital diseases are still a major problem adding to the number of disabled persons. Evaluation of mental backwardness is a big challenge with different social background, economic factors, extended family systems, low literacy rates, and virtually different habits/ADL. Mental backwardness is a disability characterized by significant limitations both in intellectual functioning and in adaptive behavior and may present as deficits in conceptual, social, and practical adaptive skills. This disability originates before the age of 18 years. It is a variable, heterogeneous manifestation of central nervous system dysfunctions, occurring in 1 to 3 percent of general population.

An estimated 10 percent of the world's population experiences some form of disability or impairment (WHO Action Plan 2006-2011). Global prevalence: 4 to 10 percent (Yeo 2001) 4 percent in developing countries and 7 percent in industrialized countries (Metts 2000) India and South Asia prevalence: 1.5-21.3 percent in WHO South East Asia member countries (<http://www.searo.who.int/>). 8 to 2.2 percent for India (Census 2001, NSSO 2002). Different prevalence rates for disability are available in India. According to the Census 2001, there are 2.19/thousand people with disabilities in India who constitute 2.13 percent of the total population (Census 2001). Out of the 21,906,769 people with disabilities,

12,605,635 are males and 9,301,134 females and this includes persons with visual, hearing, speech, locomotor and mental disabilities (Census 2001).

DIAGNOSIS

According to the latest edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV), three criteria must be met for a diagnosis of mental retardation: an IQ below 70, significant limitations in two or more areas of adaptive behavior (as measured by an adaptive behavior rating scale, i.e. communication, self-help skills, interpersonal skills, and evidence that the limitations became apparent before the age of 18).

It is formally diagnosed by professional assessment of intelligence and adaptive behavior. The following ranges, based on standard scores of intelligence tests, reflect the categories of the American Association of Mental Retardation, the Diagnostic and Statistical Manual of Mental Disorders-IV-TR, and the International Classification of Diseases.

Class	IQ
Profound mental retardation	Below 20
Severe mental retardation	20–34
Moderate mental retardation	35–49
Mild mental retardation	50–69
Borderline intellectual functioning	70–84

The diagnosis is not based only on IQ scores, but the adaptive functioning is also taken into consideration. Adaptive behavior, or adaptive functioning, refers to the skills needed to live independently (or at the minimally acceptable level for age). To assess adaptive behavior, professionals compare the functional abilities of a child to those of other children of similar age. There are many adaptive behavior scales, and accurate assessment of the quality of someone's adaptive behavior requires clinical judgment as well. Certain skills are important to adaptive behavior, such as:

- Activities of daily living, such as getting dressed, using the bathroom, and feeding oneself
- Communication skills, such as understanding what is said and being able to respond/reciprocate, verbally or nonverbally
- Social skills with peers, parents, siblings and other family members.

A three-generation pedigree helps to find out mental retardation in the family, and a detailed pre-, peri- and postnatal history should help to establish a definitive cause. A dysmorphic child may be at risk from the stress of birth, and later delay may be erroneously attributed to birth injury. A careful developmental history, with emphasis on milestones, formal assessments and behavior, is also a must. Medical records should be sought or requested

to validate any diagnosis of malformations. An accurate EEG study and/or brain MRI are sometimes sufficient to suspect several well-known and relatively common disorders (such as Rett syndrome, Angelman syndrome, neurocutaneous syndromes, etc.). The degree of MR is an important indicator: the so called "chromosomal" phenotype, which is well known to accompany larger aberrations, is frequently characterized by moderate-severe MR associated with one or more of major signs, including congenital malformations. The behavioral phenotype is also distinctive for several well-known syndromic conditions, such as Williams syndrome, Angelman syndrome, Prader-Willi syndrome. Abnormalities in head size, growth parameters, and neurologic signs should also be carefully investigated.

As compared to idiopathic mental backwardness, mental retardation may occur due to a number of causes such as listed below:

- *Genetic and chromosomal abnormalities:* One of the first genetic causes of mental retardation is Down syndrome. The extra chromosome interferes with the functioning of the brain, mostly leading to interference in intellectual functioning. Other causes such as Fragile X syndrome, Hunter syndrome, Hurler syndrome, Rett's syndrome, tuberous sclerosis, defective chromosomes, chromosome deletions/translocations also interfere with intellectual performance and lead to cognitive impairments.
- *Metabolic disorders such as phenylketonuria:* Endocrinological disturbances, e.g. cretinism, cranial malformations, hydrocephalous, microcephaly, all result in intellectual deficiencies of varying degrees.
- *Nutritional deficiencies:* Nutritional deficiencies are one of the biggest culprits of many a medical condition. A nutritional deficiency during pregnancy can be more disadvantageous to the unborn child than it can be to the mother. A lack of nutrients like vitamin A, iron, iodine, zinc, etc. has been known to cause problems pertaining to mental health for a large population across the world. With a mounting consumption of fast food/junk food, nutritional deficiencies are on the rise like never before. Apart from the above-mentioned, famine/conditions causing malnutrition is also one of the largest causes of this mental condition.
- *Environmental conditions and exposure to toxins:* One of the most important factors leading to mental retardation is those of environmental conditions, as well as exposure to toxins. Environment can impact by virtue of poverty and cultural deprivation. This idea also refers to the lack of mental stimulus, thus stunting mental growth. Exposure to toxins is an equal culprit leading to it too. One of the more common forms of these toxins would happen to be cigarettes. Expectant mothers who smoke are also a threat.

- Other conditions leading to mental retardation also are, traumatic conditions faced during pregnancy, problems at or after birth, metabolic disorders, infections, as also a multitude of unexplained reasons.

PROBABLE ETIOLOGY FOR THE IDIOPATHIC MENTAL BACKWARDNESS

- *Microdeletion/microduplication syndromes:* In the last few years, several emerging clinical entities have been described, due to the advent of newest genetic techniques, such as array comparative genomic hybridization. The detection of cryptic microdeletion/microduplication abnormalities has allowed genotype-phenotype correlations, delineating recognizable syndromic conditions. The presumed channel at the basis of remaining "pure idiopathic" forms of mental retardation, highlight possible environmental and epigenetic mechanisms as causes of altered cognition. With the advent of novel genetic techniques, several new cryptic chromosomal aberrations have been discovered in last few years and a consistent number of MR cases, previously considered "idiopathic" forms, are now classified as syndromic conditions with clinical recognizable phenotypes.
- *Parents with intellectual disability:* Studies of children raised in homes where both parents were retarded revealed that between 39 to 61 percent of children tested were retarded. In studies such as Halperin 1945, and Penrose 1963, nonretarded children tended to have borderline intelligence with IQ's varying between 70 and 90 in nearly 16 to 40 percent of cases whereas between 4 to 26 percent of children were of average intelligence. For purposes of general estimate these studies indicated that where both parents were retarded, nearly one-half had borderline intelligence and about 1/6th would be normal. Average IQ's of 65 and 74 have been noted among children of such parents (Reed and Reed 1965). The distribution of IQ's in these children, though not lending itself to any judgement as to the role of psychological factors because of the confounding effects of heredity does indicate that intelligence cannot be solely a function of the environment.
- *Home environment:* Yeates et al (1983) conducted a study to investigate maternal IQ and home environment as determinants of early childhood intellectual competence. Children at risk for socio-cultural mental retardation were studied longitudinally from birth to 4 years of age. Maternal IQ's were assessed before the child's birth and children's IQ and home environment were assessed at regular intervals during first 4 years of life multiple regression analysis was used to separate the contributions of maternal IQ and home environment to the child's IQ at 24, 36 and 48 months of age. The overall pattern suggested a monotonic increase in the predictability of the child's IQ within the context of a shift in the relative importance of maternal IQ and home environment as predictors.
- *Family size:* Another very important confounding factor has been the family size. One of the earliest and most consistently reported findings related to the effects of family size has been a decline in the IQ with an increase in the number of children. The majority of studies conducted in several nations have shown a negative correlation between family size and IQ with some indication, however, that this correlation may be less pronounced in higher socioeconomic status groups. Attempts to account for this decline in IQ with an increase in family size have generated a variety of hypothesis. All kinds of resources like financial, dietary, spatial, emotional are shared by more members in large families. In the lower socioeconomic classes, adverse physical conditions may be aggravated when many members of the family have to share a meagre subsistence. The increased size of the family also means that each child receives less attention from his/her parents and learns about life and the outer world more from the siblings who may be just a little older than the child himself. In a large family a child's development may also be affected because of the fact that so many of the role models are children themselves who use speech poorly. The decline in the IQ with increasing size of family in lower socioeconomic group mostly suggests that children from larger families would on an average be less successful academically. It would appear that compared to their IQ level, their academic achievement is much inferior. Many studies suggest that children from smaller families show higher achievement, motivation and superior performance in academics than those from larger families. Parents with higher educational and occupational aspirations for their children are likely to plan their family to match their resources. They are also likely to set goals for their children and impose standards of excellence beyond those imposed by parents who have fewer ambitions for their children. The primary effect of family size may be seen in respect of the physical development of children from large families which seems more problematic than that of children from smaller families. The probability of intra uterine problems rises with increasing number of child births. Passamanick et al 1956 reported a 10-fold increase in mental backwardness as one moves from the first to the sixth child born to the mother. In general, prematurity and its associated problems and maldevelopment also become more frequent with increasing number of child births.

- *Effect in siblings and relatives:* Idiopathic mental retardation has been documented in siblings and relatives in few studies. A genetic study of children in Birmingham Coventry has shown a recurrence risk of idiopathic mental retardation in siblings lying between 1 in 4 and 1 in 5. There was also a prevalence of mental retardation in other relatives that was greater than the population prevalence, and was less for second degree relatives than for first degree, and less still for third degree relatives. Recurrence in siblings was greater if more than one first degree relative was affected. There was no suggestion of a contribution by X-linked genes, once the fragile X syndrome had been excluded. The presence of perinatal and other environmental factors in the index children did not alter the recurrence risk for sibs except for very low birth weight. The results of many studies with pairs of siblings are similar and show that the higher the proportion of genes shared by two relatives, the higher the average correlation between their IQs. There was a low recurrence rate of mental retardation in Asian families, suggesting that they had a different distribution of intelligence from non-Asian families. Hereditary factors in the etiology of idiopathic autism are well established but particular genetic mechanisms have not been identified.

The study by Sarah Bunde et al in 1989 suggested that 60 to 70 percent of the total variation of intelligence in a population is the result of genetic factors and less than 10 percent the result of environmental factors outside the family. The genetic component is largely polygenic, that is, composed of many genes individually of little effect. Bouchard and McGue considered that there was no evidence of a contribution by X-linked genes, because like sex pairings did not differ from unlike sex pairings. However, an X-linked gene for spatial ability has been postulated. The relative contributions of genetic and sociocultural factors to the normal range of intelligence have been discussed by many authors.

- *Social impact:* Siblings of cases of ADHD have been documented to exhibit similar symptoms and lower academic performance due to behavioral and social adaptation difficulty. The family of a child with hyperactivity, attention deficits, and cognitive impairment must cope up with frequent and exceptionally high demands of parenting. The family is confronted with serious medical and environmental issues that rarely seemed to be solved.

COMORBID CONDITIONS

Conditions where mental backwardness has been documented, especially in children are listed below:

- *Mood and anxiety disorders:* Some of the common mental illnesses come under this category. Mood disorders (otherwise called affective disorders) include

conditions that are caused by persistent and extreme mood swings, like excessive happiness or sadness. Examples include depression, bipolar disorder, seasonal affective disorder (SAD), dysthymia, etc. Anxiety disorders are conditions characterized by excessive and abnormal fear and anxiety. The symptoms of these conditions can be so mild that others might not even suspect that the patient has any mental disorder. But, in some cases, the symptoms can affect the day-to-day activities, cognitive functioning and lead to a total disability. While some people develop such disorders after going through traumatic events, or can also be genetic or congenital or can be idiopathic too.

- *Specific learning disability:* It is a heterogeneous group of disorders manifest by significant difficulties in the acquisition and the use of listening, speaking, reading, writing, reasoning, or mathematical abilities. These disorders are intrinsic to the individual, presumed to be due to central nervous system dysfunction, and may occur across the life span. Children with a specific learning disability usually have a borderline to dull average intelligence. Problems in self-regulatory behaviors, social perception, and social interaction may coexist.
- *Mental retardation:* Educational and occupational histories are valuable in this regard. The patient should be asked at what age they achieved their highest educational grade, to ascertain whether they progressed normally through school.
- *Psychotic disorders:* This group includes certain types of mental illnesses that severely affect the brain and thinking process. These children/adolescents have difficulty thinking rationally and their judgments are impaired. Living their daily life becomes very, very difficult. The most prevalent symptoms of these mental disorders are delusions and hallucinations. Those affected with these disorders develop false beliefs (delusions) and perceptions (hallucinations—false sensations, like hearing or smelling something that is not there). Some other symptoms are strange behavior (may be dangerous to themselves or others), lack of personal hygiene, decreased interest in doing things, strange speech patterns that are not understandable, mood swings, relationship difficulties and slow or strange movements.
- *Psychiatric illness:* Organic illness can mimic many symptoms of psychiatric disease, especially the psychoses; some psychiatric illness may prevent adequate evaluation of a patient's intellectual functioning.
- Although loss of recent memory (learning capacity) is not a necessary accompaniment of organic mental illness, it is not seen in functional states. If adequate testing can be done, the finding of a definite recent memory deficit strongly militates against a diagnosis

of functional disease. The two major exceptions are depressive pseudodementia and malingering.

- Regressive reflexes are indicative of organic disease.
- Urinary incontinence is rarely seen in adults with functional disease.
- *Confusional states*: Deficits in maintaining attention may markedly reduce intellectual functioning. Many metabolic dementias (such as hepatic encephalopathy, delirium tremens, and cognitive deficits produced by many drugs) are manifested principally by the inability to attend to important stimuli. Lesions affecting the brain stem or thalamic reticular formation, if insufficient to produce stupor or coma, result in an attentional deficit. In general, these are referred to as confusional states or “encephalopathy”.
- *Organic psychoses*: Diseases affecting the limbic system or related structures may produce a wide variety of psychiatric findings. Persons with temporal lobe epilepsy commonly have low intellectual performance with behavioral disturbances, temporal lobe lesions or damage to the medial hypothalamus may trigger aggressive behavior; memory loss and low intelligence potentially accompanied by changes in appetite for food and sex. Damage to the left frontal lobe often produces depression, while the right frontal lobe can trigger mania.

MANAGEMENT

The primary goal of treatment is to develop the child's potential to the fullest. Special education and training may begin as early as infancy. This includes social skills to help the person function as normally as possible. It is important for a specialist to evaluate the person for other affective disorders and treat those disorders. Behavioral approaches are important for people with mental retardation.

Outlook (Prognosis)

The outcome depends on:

- Opportunities provided to the child with respect to his home environment, family support, community support
- Comorbid conditions and associated psychiatric disorders
- Personal motivation
- Therapeutic interventions in the form of speech therapy, physio-occupational therapy, special education

guidance, etc. Many persons can lead productive lives and function on their own; many others may require a structured environment to be most successful.

CONCLUSION

Pediatricians should be alerted by the presence of MR of unexplained origin associated with altered auxological parameters, multiple congenital defects, neurological and psychiatric signs, and/or minor dysmorphisms. The implementation of the so called “next generation sequencing” technologies (that allow the analysis of whole-genomes, transcriptomes and interactomes) could lead to detect single base mutations and structural variations, further broadening the possibility of diagnosis in “idiopathic” cases of MR. Understanding the pathological pathways underlying unexplained forms of MR represent a future challenge to increase both prevention and possible therapies. Because of the high incidence of CNS impairment and low overall interpersonal coping abilities, children/adolescents with mental backwardness have a greater than average risk for developing associated psychiatric disorders. Persons suffering from such a condition require constant care, intervention and custom-made system of education. Resources and services for mental and behavioral disorders are disproportionately low compared to burden caused by these disorders the world over. In most developing countries, care programs for the individuals with mental and behavioral problems still have a low priority. Provision of care is limited to a small number of institutions usually overcrowded and under staffed. Over past several decades, the model of mental health care is changing and community care approach is setting in. The mental health programs have played important role in this shifting paradigm. Early intervention and early stimulation programs are playing a vital role in the various Child Development Centres being set up across the country.

INTRODUCTION

Constipation is a symptom of underlying disorder and is more common in males as compared to female children. It is a very common problem in pediatric age group. 10 to 25 percent of all patients attending pediatric gastroenterology clinics are constituted by various fecal elimination disorders. About 1.3 to 5 percent of children suffering from chronic constipation have problem of encopresis. Chronic constipation is a real challenge to the parents, children as well as for the pediatricians to understand and to treat it effectively. The presence of encopresis adds to the parental anxiety and has a great impact on the overall development and social acceptance of the child. Chronic constipation has great impact on the education, personality, psychological well being and growth of the child. Children are usually isolated, cranky, irritable and lack concentration. The quality of life suffers a lot. So there is need of meticulous and well planned approach to manage a child with constipation.^{1,2}

PREVALENCE

Constipation is a very common problem encountered in pediatric gastroenterology clinics, constituting 10 to 25 percent visits whereas it is 3 percent in pediatric outpatient clinics. The problem is alarming and distressing frequently dealt by various disciplines like primary care physician, emergency general pediatrician, pediatric surgeons and pediatric gastroenterologists.

Prevalence varies with the age, usually peaks around 2 to 4 years when toilet training is often defective. The prevalence during first year is 2.9 percent, during 2nd year is 10.1 percent and in school age is 17.5-34 percent. In adult population it is 10 percent.³⁻⁵

DEFINITIONS

Constipation

Constipation is defined subjectively as a feeling of unsatisfactory evacuation. The other accompaniments could be passage of too small stool, too hard stool, too difficult to expel, too frequent and incomplete evacuation. But the objective and well accepted definition of constipation is passage of stools twice or less per week.

Based upon the symptomatology certain criteria have been used in literature to define constipation. According to the guidelines of the North American Society of Pediatric Gastroenterology, Hepatology and Nutrition (NASPGAN), the constipation is defined as a delay or difficulty in the act of defecation present for 2 or more weeks and sufficient to cause significant distress to the patient. Loening-Baucke criteria also called as Iowa criteria given in Table 1 to define constipation have been used widely in various studies. According to this constipation is labeled when two out of the following symptoms are present in last three months: (1) less than 3 bowel movements per week, (2) encopresis more than once per week, (3) large amounts of stool every 7 to 30 days (large enough to clog the toilet) and (4) palpable abdominal or rectal mass on physical examination.³⁻⁵ Recently an attempt has been made to define the functional gastrointestinal disorders in children called Rome II criteria as in Table 2. But these criteria are too cumbersome and are difficult to follow in general practice and are not of much help. Paris Consensus on Childhood Constipation Terminology (PACCT) group has offered working definition of chronic constipation in children. The chronic constipation is defined based upon the defecation characteristics during last 8 weeks 7 given in Table 3.

Table 1: The Loening- Baucke criteria of pediatric constipation

At least two of the following criteria:

- Defecation frequency less than 3 times a week
- Two or more encopresis episodes per week
- *Periodic passage of very large amounts of stool once every 7-30 days
- A palpable abdominal or rectal mass at physical examination

*The criteria of a large amount of stool is satisfied if it is estimated to be twice the standard amount of stool, shown in a clay model, or if stools are so large to clog the toilet

Table 2: Childhood functional defecation disorders: Rome: II criteria*Infant dyschezia*

At least 10 minutes of straining and crying before successful passage of soft stools in an otherwise healthy infant

Functional constipation

In infants and preschool children at least 2 weeks of:

- Scybalous, pebble like, hard stools for a majority of stools; or
- Firm stools two or less times/week; and
- No evidence of structural, endocrine, or metabolic disease

Functional fecal retention

From infancy to 16 years old, a history of at least 12 weeks of:

- Passage of huge diameter stools at intervals <2 times/week
- Retentive posturing, avoiding defecation by contracting pelvic floor and gluteal muscles

Functional non-retentive fecal soiling

In children older than 4 years a history of once a week or more for the preceding 12 weeks of:

- Defecation into places and at times inappropriate to the social context
- In the absence of structural or inflammatory disease and
- In the absence of signs of fecal retention

Table 3: The PACCT definition of chronic constipation

When 2 or more of the following characteristics during last 8 weeks

- Frequency of bowel movements less than three per week
- More than one episode of fecal incontinence per week
- Large stools in the rectum or palpable on abdominal examination
- Passing of stools so large that they obstruct the toilet
- Retentive posturing and withholding behavior
- Painful defecation

Table 4: Classification of constipation

- I. Depending upon the age of onset
 - a. Congenital constipation (Since birth)
 - b. Functional constipation
- II. Depending upon the duration
 - a. Acute or simple constipation (2 weeks-8 weeks)
 - b. Chronic constipation (>8 weeks)
 - Mild
 - No megarectum/megacolon or impaction
 - No encopresis
 - Severe (complicated)
 - Associated with megarectum and megacolon or impaction
 - Associated with encopresis

Encopresis

Encopresis is the involuntary passage of formed, semi-formed or liquid stool in the child's underwear. Largely this is considered to be functional when there is no organic or anatomic cause or medication responsible for it after the age of 4 years. This is equivalent to enuresis in children. In presence of chronic constipation it is called overflow incontinence. This is present in around 5 percent of children with constipation. Before the age of 3 to 4 years, it is very difficult to recognize because, diapers are used and moreover, voluntary control on the act of defecation may not be achieved. This emphasizes the fact that encopresis could be functional or overflow incontinence.^{1,2,8}

Fecal Soiling

Fecal soiling is any amount of stool deposited in the underwear, independent of whether functional or organic or anatomic lesion is present.

Fecal Incontinence

Fecal incontinence is fecal soiling in the presence of an organic or anatomic defects such as anal malformation, anal surgery, anal trauma, meningomyelocele and other neurological and muscle diseases affecting the anorectal area and perineum. There is no retaining capacity due to lack of reflexes involved in retention of stool and act of defecation. But some authors have used these terms interchangeably in the literature.¹

CLASSIFICATION

This is not clear from the literature. For better understanding of the problem, the suggested classification is given in Table 4. There is no ambiguity to understand the congenital and acquired constipation. Congenital constipation is usually since birth and is associated with Hirschsprung's disease (HD) and congenital anorectal anomalies. Acquired constipation occurs any time after birth, but there are no neurological and anatomical abnormalities of anorectal region. Acute constipation is defined when it is of shorter duration possibly less than 8 weeks. On the other hand when the duration of constipation is more than 8 weeks and is labeled chronic constipation. This may or may not be associated with megarectum and megacolon or impaction and encopresis. Chronic constipation is mild when there is no encopresis or megarectum and megacolon or impaction whereas when it is complicated by presence of

encopresis, megarectum and megacolon or impaction is termed as severe chronic constipation.^{9,10}

PATHOPHYSIOLOGY OF CONSTIPATION

Normal Bowel Habits

The normal frequency of stools varies from 3 times per day to 3 times per week. But this may be as high as 4-10 times during breast-feeding period in infancy. Toddlers may pass stools 3 to 5 times per day but as the age advances, the transit time increases and normal adulthood frequency of 1 to 2 times per day is achieved after 4 years of age.

Bowel Training

Normal bowel training should be started at the age of one year when infant starts walking. Regular timing and passage of at least one stool per day are essential for the normal function of the bowel. For this use of appropriate potty or toilet where a child can sit in squatting position is required. Mother should ensure child sits comfortably on the lavatory seat without fear.

Mother should use one word for defecation training and if baby repeats this is a good sign. Child should be made to sit for 5 to 10 minutes. Normally children start attending toilet independently by the age of 2-3 years. Problems in the bowel training can arise because of dietary changes, low fiber diet, formula feeds, anal fissure, inter-current illnesses, travel, moving to new home, family dysfunction, birth of sibling, erroneous parents expectation, family problems, failed toilet training, unresolved stress in school, changing of school, privacy, drugs and various neurological disorders. Most of the times these precipitating factors are responsible for onset of constipation with some functional overlay.¹²⁻¹⁵

Physiology of Defecation

Infants have involuntary passage of stools and there is no control on defecation. They may cry or make some movements while passing stools. Mostly they pass stool while feeding due to exaggerated gastrocolic reflex. After the age of one year the voluntary control starts developing and by the age of 1½ to 2 years they have the control and tell about the act of defecation. This is achieved earlier in girls as compared to boys. By the age of one year the mother starts training the child to follow one word to pass stool. The good and early control depends upon the training by mother and the positive response by the child.

Normally the mass movements occur 3 to 4 times a day but only 1 to 2 times mature for defecation. The sigmoid colon acts as store house, once stool passes into the rectum then urge to defecate is generated. There are two types of nervous systems involved, the autonomic and the sensory. The autonomic is stimulated by contact of the stool to the mucosa of rectum and afferent impulses

move to central nervous system to stimulate efferent so that internal sphincter relaxes. The internal anal sphincter is formed by thickening of the terminal inner layer of smooth muscles of rectum. Below this, there is anal canal and external anal sphincter. The striated muscles form the pelvic floor and external anal sphincter. These are innervated by pudendal nerve and 4th sacral nerve. The puborectalis muscle is the part of levator ani and at the level of internal sphincter it makes a sling around the lower part of rectum and gets inserted into symphysis pubis. This is very important muscle to form the anorectal angle to maintain the continence. Normally this angle is right angle (85-110°) and during the act of defecation the angle becomes straight or obtuse in squatting position to ensure smooth passage of the stool during defecation. Once the fecal matter descends from sigmoid colon to rectum, mere distension of rectum initiates the urge for defecation. There is relaxation of internal sphincter but contraction of external sphincter. The external sphincter can be contracted or relaxed voluntarily. If there is no conducive atmosphere the contraction leads to postponement of urge hence, more accumulation of fecal matter. If individual wishes to pass stool and sits in squatting position, the anorectal angle gets straightened, the puborectalis muscle and external sphincter relax to fire the stool in the toilet. The rectosphincteric reflex is generated by rectal distension only. The pelvic floor also descends by 1 to 3.5 cm to facilitate the passage of stools. At the same time the abdominal muscles contract and the glottis is closed to generate the intra-abdominal pressure to push the stool in a smooth fashion. The abnormality at any of the levels of act of defecation results to dysfunctional fecal elimination disorders. The constipation is the most important problem to develop.^{9,11}

PATHOGENESIS OF CONSTIPATION

Constipation during childhood is confluence of variations in physiological tendencies like development transitions, environment factors and parental response. Most of the times constipation is a problem in toddlers and this may become passive if tackled in time. There is always a precipitating cause.

Infancy

During infancy the constipation is mostly pathological due to Hirschsprung's disease, anorectal problems, mental retardation or anatomical abnormalities of anorectal area. This may also be due to formula feeding and lack of cereal supplementation after 6 months of life. Infants largely on animal or formula milk feeds and on low fiber diet are prone to develop constipation. Lack of breast feeding predisposes the infants to develop constipation due to top milk feeds. Sometimes janam gutti and opiate

Fig. 1: Pain a common factor in constipation in toddlers

like drugs given by parents may be responsible for constipation in infants.^{16,17}

Toddlers/Preschool Children

In toddlers the most important factor is the painful act of defecation due to anal fissure. The head of the stools is always hard and can injure the anal canal leading to fissure formation. The anal fissure is very painful. Child tries to defer next act of defecation, and goes on withholding the stool as there is fear of pain to the next act of defecation. The anal injury occurs due to passage of hard stool and later on this gives rise to retention and pain cycle given in Figure 1. This goes on and results into chronic constipation. Children start adopting different postures to evacuate. This leads further injury to anal canal. As they start going to school other confounding factors come in operation. The most important confounding factor is the low fiber diet in form of junk foods, soft drink beverages and bakery products available in ready made form in the market. The children have more liking for these foods and they dislike fiber rich home made diet. Parents have no time to feed their children with home made stuff. Moreover the media is highlighting junk foods in a big way to exploit the children. Prolonged fecal impaction leads to chronic rectal distension and loss of rectal sensation so there is further stool impaction resulting in megacolon and megarectum to accommodate large volume of stool. The retention of large volume of stool is responsible for pain abdomen and encopresis or soiling in the underwear subsequently. The other most important factor is lack of toilet training after the age of 1 year. If it remains unsupervised due to the lack of interest by mother, it results in constipation.

School Children

The lack of privacy and positive reinforcement leads to problem of chronic constipation. Psychologically children are withdrawn and develop other functional problems also.^{2,3} This is more common in female children who do not find appropriate hygienic toilets and bath rooms in the school. Various other causes of acute and chronic

Table 5: Etiology of acute constipation in infants and children

<i>Infants:</i>	<i>Toddlers and older children</i>
Lack of breast milk	Change of diet
Formula feeds	Change of place
Cow milk based diet	Traveling
Change of diet	Anal fissure
Low fiber diet	Boil
Anal fissure	Abscess
Inflammation in perianal area	Infected hemorrhoids
Boil	Dermatitis
Dermatitis	Low fiber diet
Drugs: Opiates, <i>Janam gutti</i> , etc.	Drugs

constipation in children are given in Tables 5 and 6 respectively.¹⁸⁻²⁰

Associations of Chronic Constipation

Children suffering from recurrent abdominal pain (RAP), 50 percent may be constipated and 20 percent of them may show psychiatric problems. Chronic constipation may be associated with irritable bowel syndrome (IBS).

With the impaction of stools other associations are enuresis, UTI, palpable mass, soiling/encopresis/overflow incontinence, finger evacuation, solitary rectal ulcer, rectal prolapse, irritability, scissoring of legs, passage of stool while standing (unphysiological way to pass stools). Usually there is loss of appetite and poor weight gain.^{4,5,21}

CLINICAL PRESENTATION

The main complaint of the parents is the longer interval between bowel movements in the child. The clinical picture associated with chronic constipation includes pain abdomen, vomiting, abdominal distension, excessive flatulence, fecal soiling, prolapse and blood streaked stools. The infants and toddlers become more irritable and cranky. They are in the habit of withholding the stools and pass stool at irregular intervals. The stools may be hard and come out in form of hard large caliber casts, balls, or ribbon or pencil like. The amount may be small but at times large. They have to strain a lot to pass stools. Infants squeeze their buttocks and flex the legs and cry a lot while passing stools. The toddlers develop scissoring (cross their legs) squeeze their buttocks and strain a lot. They can not sit because of fear of pain and pass stool in standing posture behind the curtain or door or sofa in an isolated place. They are afraid of pain and do not allow to touch the abdomen and perineum.

Constant withholding of stools, leads to impaction of fecal matter and is responsible for development of encopresis. This is also called soiling in the under wears. The frequency of soiling may vary depending upon the severity

Table 6: Etiology of chronic constipation with or without megarectum, megacolon or encopresis

<i>Congenital</i>	<i>Acquired constipation</i>
<ul style="list-style-type: none"> • Anorectal defects <ul style="list-style-type: none"> Anal stenosis Anal atresia Imperforate anus Anterior displaced anus • Neurogenic <ul style="list-style-type: none"> Myelomeningocele Spina bifida • Colonic neuropathies <ul style="list-style-type: none"> Hirschsprung's disease Intestinal neuronal dysplasia • Colonic defects <ul style="list-style-type: none"> Colonic atresia Short colon 	<ul style="list-style-type: none"> • Idiopathic or functional 90-95% • Anal lesions <ul style="list-style-type: none"> – Anal fissures – Abscess – Strictures due to IBD, TB – Anal surgery/trauma/sexual abuse • Neurological conditions <ul style="list-style-type: none"> – Cerebral palsy – Hypotonia – Mental retardation – Tumor of spinal cord – Tethered cord • Metabolic <ul style="list-style-type: none"> – Hypokalemia – Hypomagnesemia – Hypophosphatemia – Hypercalcemia – Cystic fibrosis • Endocrine <ul style="list-style-type: none"> – Hypothyroidism – Multiple endocrine neoplasia IIB (MEN) – Diabetic mellitus – Hyperparathyroidism • Drug induced <ul style="list-style-type: none"> – Antimotility drugs – Anticholinergics – Antidepressants – Antihypertensives – Anticonvulsants – Opiates – Codeine – Antacids – Phenothiazines – Methylphenidate • Food allergy <ul style="list-style-type: none"> – Milk – Celiac disease • Low fiber diet • Psychiatric problems

of constipation. These children may have enuresis, UTI and behavioral problem. Children with constipation may appear quiet, withdrawn, embarrassed, agitated, clinging to mother and angry on examination as compared to children with other gastrointestinal disorders. The history of functional bowel disorder may be positive in parents at times.²²

CLINICAL APPROACH TO CONSTIPATION

History

Detail history is required to find out precipitating factors for constipation in children. While taking history special

attention should be paid towards the toilet habits, which include characteristics of stools in the toilet, in the underwear and stool withholding maneuvers. Age of onset of constipation is also important. Constipation starting from neonatal life gives clue towards developmental anomalies of anorectal area or colon. Delayed passage of meconium after 48 hours of birth gives clue of Hirschsprung's disease. Associated abdominal pain may be the sole symptom of constipation in 50 percent children with RAP. It is important to enquire about dietary habits of the child. Consumption of excess of milk, juices and/or other drinks, junk foods and bakery products may lead to constipation. In the modern era children largely depend upon low fiber diet and this becomes important factor for onset of constipation. Less consumption of cereals, pulses, vegetables and fruits can result in constipation. Inadequate and low fiber diets are responsible for less production of stool. History of medication/drugs should be asked. One must also enquire about the associated conditions like enuresis, UTI or any psychiatric problems. There is loss of appetite due to delayed stomach emptying and slow transit time due to colo-gastric reflex. There may be poor weight gain.^{5-9,23} There is strong association of constipation or other functional GI disorders in the parents or other sibs.

Examination

Patients should be thoroughly examined including growth parameters, nutritional status, general physical examination, neurological examination, abdomen and perianal area. Abdominal examination may reveal a lump in the left iliac fossa or suprapubic area due to retention of fecal matter in the sigmoid and descending colon. Sometimes whole of the colon may be palpable. Perianal examination may reveal anal anomalies or boil or fissure. Rectal digital examination should be carried out. In case of acquired constipation hard fecal matter is felt just at the entry of the finger in the anal canal on digital rectal examination. In case of HD the rectum is empty, whereas the fecal matter is felt high up and on withdrawal of finger fecal matter may gush out. In case of anal stenosis, there will tight opening. In presence of active anal fissure digital rectal examination should be avoided because this can enhance the anal injury. Neurological examination including inspection of lumbosacral spine, lower limbs and perianal sensation testing should be done.

Investigation

In case of functional chronic constipation there is no need of elaborate investigation. The history and examination give clue to the diagnosis of most of the anatomical defects responsible for constipation. History of food allergy especially milk and celiac disease may be responsible for this. There are other causes of constipation in childhood as mentioned in table and should be investigated as below.^{24,27}

Plain X-ray Abdomen

Abdominal radiographs should be done in erect and supine position to see for the extent of fecal load and to delineate the dilatation of rectum and colon. There may be impaction with megarectum and megacolon. In case of HD and other congenital anomalies the rectum and colon may be hugely distended. At times fecoliths may be seen. The spinal abnormalities like spina bifida or neural tube defects can be diagnosed.²⁴⁻²⁷

Endocrine Assessment

Thyroid function tests should be done to rule out hypothyroidism. Serum calcium levels and parathormone levels are required if there is suspicion of hyperparathyroidism. If there are osmotic features rule out diabetes mellitus.

Metabolic Work-up

To rule out certain metabolic disorders as given in table serum potassium, magnesium, phosphate, calcium, sweat chloride and tissue transglutaminase antibodies should be ordered based up the high index of suspicion.

Anorectal Manometry

This is not done routinely but if there is suspicion of HD then it is indicated.

Barium Enema

In HD there is contracted segment and above that there is huge dilatation of bowel due to obstruction.

Rectal Biopsy

This is important to diagnose HD. The absence of intramural ganglion cells is the diagnostic of HD and biopsy should be taken from rectum above the pectinate line.

Transit Time Study

Some of the patients may have delayed transit time of the bowel. This is measured by giving radio-opaque markers and seeing their elimination over the time. The significance of this is not clear in pediatric age group.

Most of the times, detailed clinical examination of patient gives clue to the anatomical defects/neurological causes of constipation. Drugs responsible can also made out on history only. The points to differentiate acquired constipation and Hirschsprung's disease are given in Table 7. The childhood constipation differs from that of adolescent/adulthood constipation and the differences are given in Table 8. A meticulous practical approach to management of chronic constipation is shown in Flow chart 1. The algorithmic approach is based upon clinical presentation, investigations and treatment.

MANAGEMENT OF CHRONIC FUNCTIONAL CONSTIPATION

Certain principles of management of chronic constipation are very important to ensure drug therapy and its compliance. The treatment of functional constipation is discussed under the following headings.

- General measures
- Pharmacotherapy
- Treatment modalities

General Measures

There are many apprehensions in the minds of parents and the child. The children have emotional and behavioral problems, prolonged school absence and social factors and parental conflicts. Based upon these facts the following interventions are very important.^{2,11}

Table 7: Difference between functional constipation and Hirschsprung's disease in children

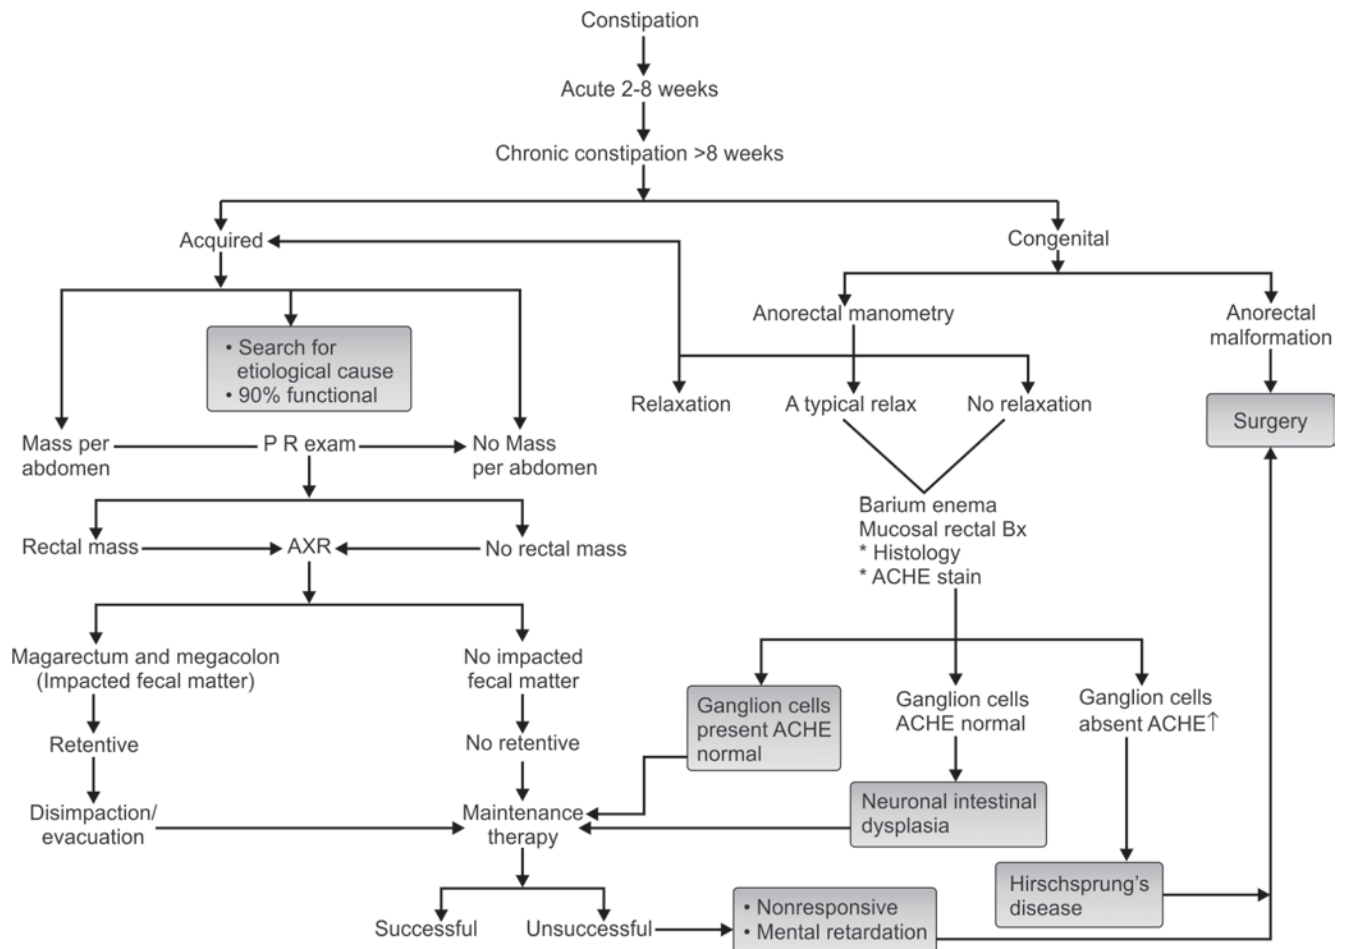

Features	Functional constipation	Hirschsprung's disease
• History		Common
Onset at birth	Never	Unusual
Retentive posturing	Common	Rare
Encopresis	Common	Unusual
Large caliber stools	Common	Common
History of obstruction	Rare	
• Physical examination		
Failure to thrive	Unusual	Common
Distended abdomen	Occasional	Common
Stool in ampulla	Common	Rare
Rectal ampulla	Dilated	Narrow
• Investigations		
X-ray abdomen	Fecal impaction, dilated rectum and colon	Hugely dilated colon with fecal matter
Barium enema	No narrow segment, rather dilated rectum and colon	Narrow segment with proximal dilatation
Rectal biopsy	Normal ganglion cells and ACHE*	Absent ganglion cells and increased ACHE*
Rectal manometry	Normal	Abnormal contraction

* ACHE: Acetylcholinesterase

Table 8: Difference between childhood and adolescent/adulthood with constipation

Features	Children	Adolescents/adults
Occurrence	More common in male	More common in female
To begin with	Toilet training and school entrance	Adolescence, young adulthood
Defecation behavior	Withholding	Straining
Scissoring and to pass stool in standing posture	Common	Sit in squatting position and strain lot
Encopresis	Common	Rare
Use of medications or due to systemic disease	Rare	Common
Barium enema	Rule out Hirschsprung's disease	To rule out intra-abdominal pathology
High fiber diet	Rarely helpful	Helpful
Role of biofeedback	Controversial	Beneficial in pelvic floor dyssynergia
Role of surgery	Only in HD* and in anorectal anomalies but not in functional constipation	May be helpful in slow transit constipation

*HD: Hirschsprung's disease

Flow chart 1: Practical approach to constipation

Education

The actual problem of constipation, its causation and anatomy of large bowel should be explained to parents and the older children. The mechanism of act of defecation and pathophysiology of constipation should also be explained to the parents. This will take care of conflicts in form of blame and guilt between parents and the child. This will encourage the parents to institute the effective therapy.

Behavioral Advice

It is important to gain the trust of the child. Child should be assured of the treatment to take care of his problem. Parents should ignore the failures rather reward for the success. Child should be boosted and encouraged to have more success in the defecation disorder including soiling. This will ensure the meaningful treatment as fear in the mind of the child disappears.

Toilet Training

This is very important component of the treatment where there is deficiency in the toilet training. Child should be encouraged to sit in the toilet in a comfortable position at the time of urge of defecation. This should initially be ensured in the morning, evening and after the meals. Make sure the child sits in the toilet with ease with adequate foot support. This will ensure the smooth flow of the stools.

Reward Schemes

Reward schemes are helpful in the behavioral management of the problem. Small rewards in form of daily requirements of the child are important when the child passes stool successfully.

Reassurance and Encouragement

Parents are to be reassured that constipation is very common problem and outcome of treatment is good if there is good compliance. They should be encouraged for close follow-up.

Diet, Fluids and Exercise

Adequate diet rich in fiber is advised. This will ensure the decrease in transit time. Adequate fluid intake will ensure proper hydration of body and help in evacuation. The daily exercise in form of active participation in outdoor activities will help in better elimination of stools. Toilet training, incentive and reward schemes, desensitization of toilet phobia and cognitive therapies like psychotherapy, cognitive and family therapies do help to have better response and good outcome.

Counseling

Counseling of parents is very important regarding the problem and its treatment. Certain differences among the

child and parents must be taken care of. They should be explained about the availability of treatment. Moreover treatment lies in their hands as they are going to handle the treatment at home. The treatment required is for prolonged period, may be for six months to one year or even longer. The importance of close follow-up is mandatory to ensure successful treatment.

Pharmacotherapy

Various agents used in treatment of constipation are divided in various groups have been given in a tabular form (Table 9).

Osmotic Agents

Lactulose

Lactulose is a very often used to treat constipation in children. Lactulose is a disaccharide of sugars D-galactose and D-fructose and is not absorbed in the intestine. The enzymes in the gut cannot digest it and it reaches the colon as such. There it is acted upon by colonic bacteria. The byproducts of this action lead to increase in fecal bulk and gas stimulates the peristalsis. There are no placebo control trials, however its efficacy in treatment of mild constipation has been reported in children. Lactitol, another form of lactulose, is equally effective. Lactulose can lead to minor side effects in form of abdominal discomfort, flatulence and bloating.³⁵

Polyethylene Glycol

Polyethylene glycol (PEG) 3350 is an osmotic agent. It is not absorbed in the gut due to its large molecule size. This makes the bulk of the stool by not allowing the water absorption. This is very effective. There are case controlled well conducted studies. It is much more superior to lactulose and magnesium hydroxide (milk of magnesia). It is used for disimpaction as well as for maintenance therapy. Its efficacy and safety even for more than 3 months has been well documented. Polyethylene glycol (PEG) electrolyte solution is often used for bowel preparation before colonoscopy and is very effective. It can be used for treatment of constipation but is very cumbersome and may lead to metabolic disturbances, when used for longer time. Polyethylene Glycol (PEG) 3350 is easy to use and very effective as compared to PEG electrolyte solution.²⁹⁻³⁵

Lubricants

Liquid paraffin is a mineral oil and a petroleum derivative. It is popularly used for treatment of chronic constipation. It softens the stool by lubrication and there is osmotic effect also due to conversion of oil to fatty acids. Liquid paraffin is effective for disimpaction as well as for maintenance therapy of chronic constipation as shown in various trials. It is associated with aspiration lipoid pneumonia in younger children. Its use is not recommended for children

Table 9: Commonly used oral laxatives in childhood constipation

<i>Agents</i>	<i>Dosages</i>	<i>Side effects</i>
Osmotic		
Lactulose/lactitol/sorbitol/ mannitol	Maintenance 1-3 ml/kg/day in 2 doses	Bloating, cramps, diarrhea
Magnesium citrate	Maintenance 1-3 ml/kg/day in 2 doses	Hypermagnesemia, hypophosphatemia and secondary hypocalcemia
Magnesium hydroxide (Milk of magnesia)	Maintenance 1-3 ml/kg/day in 2 doses	
Polyethylene glycol (PEG) 3350	Disimpaction: 1.5 g/kg 1 day in 240 ml water X 3-4 days	Nausea, vomiting, cramps and diarrhea
Polyethylene glycol Electrolyte solution	Disimpaction: 14-50 ml /kg/h till clearance Maintenance: 5-10 ml/kg/day	
Lubricant		
Mineral oil (liquid paraffin)	Disimpaction: 15-30 ml/year of age Maintenance: 1-3 ml/kg/day in 2 doses Oral 100 mg twice a day can be used as enema	Aspiration risk Lipoid pneumonia, nausea
Sodium docusate		
Stimulants (given for short course)		
Sodium pecosulphate	5-10 mg daily	Cramps, diarrhea
Bisacodyl oral and enema	5-10 mg daily oral 5 mg per rectally	Cramps, pain abdomen and anal irritation
Glycerine suppository	Pediatric suppository up to 6 years, adult sup- pository >6 years	Anal irritation
Sodium biphosphate enema	Disimpaction: 6 ml/kg/12 hourly 3 times	
Senna	2.5-7.5 ml/day (2-6 years) 5-15 ml/day(6-12 years)	Melanosis coli, hepatitis
Castor oil	Disimpaction: 15-30 ml/day	Cramps, severe diarrhea
Bulk laxatives		
Psyllium (Isbagol), Methylcellulose, Polycarbophil	Maintenance dose: Daily requirement Age in years + 5 = g/day Titrate up to 20 g/day	Bloating
Prokinetic drugs		
Cisapride	0.5-1 mg/kg body weight in diabetes, pseudo- obstruction	Diarrhea

having gastroesophageal reflux and/or aspiration and in children less than 3 years age. Tolia et al studied efficacy of mineral oil versus PEG 3350 and found both are effective for disimpaction and for the maintenance treatment of chronic constipation.²⁸ Compliance was better with mineral oil whereas fecal impaction clearance was good with PEG 3350.

Stimulant Laxatives

These include senna, bisacodyl, sodium dioctyl sulfosuccinate (also a stool softener) and sodium picosulphate. They stimulate the peristalsis and increase the intestinal motility. They are widely used and are safe and effective.

But their use is not based on evidence based medicine. There are no trials on these agents to follow guidelines. Short-term use in the evening to have better clearance in the morning is beneficial in older children. They can lead to colicky abdominal pain. These can be used to prevent relapse intermittently.

Enema

Enema therapy is required when oral medication has failed to give relief to the child with impacted stools. Routinely, should be avoided as this gives a traumatic experience to the child and can exacerbate the stool withholding behavior. There are no trials of enema therapy in children. Phosphate enema can lead to metabolic changes.^{1,11}

Bulk Forming Agents

Low intake of dietary fiber has been well known to lead to constipation in children. The best examples in children are milk based diet and junk food/bakery food. Increase in diet rich in fiber does help to relieve the constipation. The bulk forming laxatives are psyllium (isabgol), methylcellulose, polycarbophil and glucamannon (fiber gel polysaccharide). The role of fiber in chronic constipation has been evaluated and has been found to be a good adjunct to laxative therapy. Certainly diets rich in fiber like vegetables, salads, fruits, pulses with husk and raw grains (dalia) are advised as part of treatment and do help with laxative agents. Wet fiber is preferred over dry fiber in children.

Prokinetic Agents

Cisapride has been found to be helpful but its use has been banned due to side effects. Another drug erythromycin acts by stimulating motilin like receptors on smooth muscle cells and cholinergic neurons in gastrointestinal tract. The trials in small number of patients have shown to be effective but larger trials are required. These are helpful in motility problems has been associated with diabetes mellitus and chronic intestinal pseudo-obstruction.

Probiotics

The role of probiotics has been studied in constipation in relation to irritable bowel syndrome but its efficacy has not been defined in childhood chronic constipation. Studies are required to define efficacy in childhood constipation.

Newer Drugs

The newer drugs include tegaserod, prucalopride and alvimopan. These increase the peristalsis and the secretions to relieve the constipation but trials in children are not available. Tegaserod is banned due to its side effects.

Treatment Modalities

Acute Simple Constipation

This is very common in children, usually mild and easy to treat. Enough fluids and carbohydrate rich diet takes care of constipation in infants. Parents must be educated and reassured that it is not pathological. One has to eliminate the precipitating factor. Treat local causes like anal fissure, boil or dermatitis effectively. Procedures like enemas, finger evacuation/disimpaction, finger dilatation and frequent use of suppositories should be avoided. But encourage use of high fiber diet in terms of cereals, pulses, vegetables and fruits. Adequate fluid intake is advised to keep proper hydration. Initially laxatives can be used. Encourage toilet training simultaneously. Laxatives can be given for 7 to 10 days but prolonged use should be discouraged. If this is not properly treated can result into

chronic constipation¹¹ and may require therapy for longer time.

Chronic Constipation

Treatment of chronic constipation is possible by multimodality approach¹ and is given in Flow chart 3.

Mild Chronic Constipation

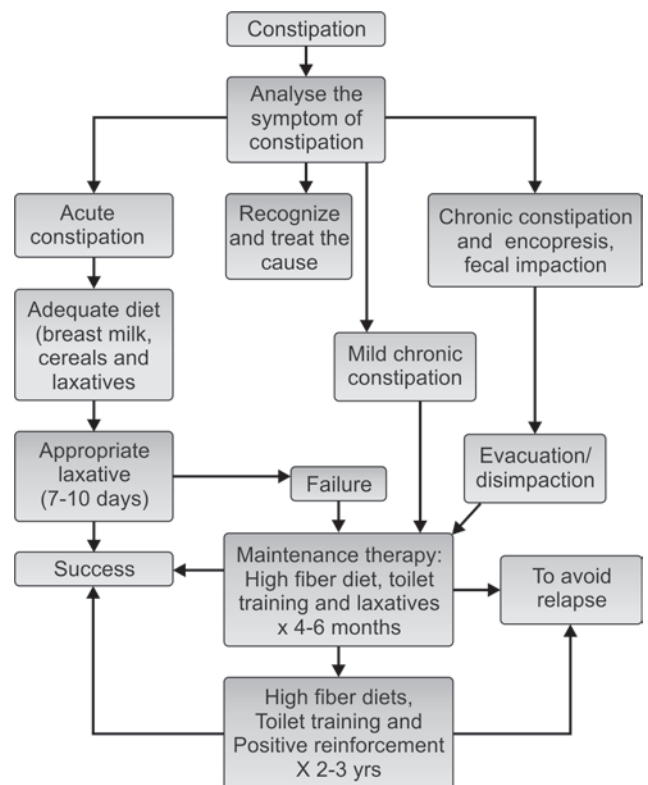

The uncomplicated chronic constipation without palpable fecal masses, megarectum or megacolon and encopresis is treated as the management protocol given under maintenance phase of treatment (Flow chart 2). There is no need of evacuation since there is no impaction.

Chronic Constipation with Impaction and Encopresis

Bowel Disimpaction/Evacuation

This is very important to have clean bowel free of retained/impacted stools. This will also take care of overflow incontinence/soiling. If initial disimpaction is not done, the treatment with oral laxatives result into paradoxically increase in overflow incontinence, increase in abdominal pain and bloating. These cases may land in the emergency ward with acute abdomen. Thus disimpaction is mandatory before starting the laxatives in maintenance phase of treatment. The disimpaction can be done by oral route, rectal route, combination of oral and rectal routes and surgical methods.¹¹ But oral route is preferred.

Flow chart 2: Management of constipation summarized

Oral Route

Total bowel wash is very effective to clear whole of colon. This can be done with normal saline or polyethylene glycol electrolyte solution in the dose of 14 to 40 ml/kg/hour till the returns are clear. Metochlopramide (5-10 mg) should be given ½ hour before the lavage to avoid vomiting. Sodium phosphate solution can be used. In case child is not able to take enough fluids orally it can be given through nasogastric tube. Clearance of colon can be ascertained by examination of abdomen for fecal masses, per rectal digital examination and X-ray abdomen.²⁸⁻³⁴

Recently it has been shown that polyethylene glycol (PEG) a non-electrolyte substance is very effective in disimpaction of the fecal mass in children. This is an osmotic agent. The dose of PEG is 1.5 g/kg/day for 3 to 4 days. This can be dissolved in 240 ml water and given orally. This is quite effective, safe and easy to use orally without much side effects. In case loose stools occur, the dose of PEG can be lowered and adjusted accordingly. The results are better with PEG as compared to lactulose.³⁵

Rectal Route

Enemas: Three hypertonic phosphate enemas 12 hourly can clear the rectum effectively. The dose recommended is 6 ml/kg/day. When the weight of the child is above 20 kg the adult dose can be given. Occasionally hypernatremia, hyperphosphatemia, hypocalcemia, hypokalemia and dehydration have occurred with hypertonic enema. Saline enema is less effective but can be used. This takes longer time to clean the colon. Plain tap water and soap water enemas are not to be used in children.^{1,11}

Suppository: Glycerine or bisacodyl suppositories can be tried in younger infants and may evacuate rectum effectively. It should not be repeated often since it can traumatize the anorectal area. The stool withholding practice by the child is exaggerated further and adds to the misery.

Purgation: Large dose of mineral oil (liquid paraffin) or castor oil or other osmotic agents can effectively evacuate rectum. Usually repeated doses are required. These are not used in children.²⁸

Surgery: Surgical disimpaction is required very rarely in severe constipation, failed medical treatment, mental retardation and fearful situation with poor compliance. Surgery is the definite treatment of Hirschsprung's disease (HD) and other anorectal congenital anomalies in children.^{36,37}

Maintenance Therapy: The goals of maintenance therapy are (1) to maintain adequate frequency, (2) to avoid continued passage of large stools and (3) to prevent withholding/retention of stools. Retraining medications include stool softeners or bulk-forming agents or osmotic agents. The laxatives used are milk of magnesia, liquid paraffin,

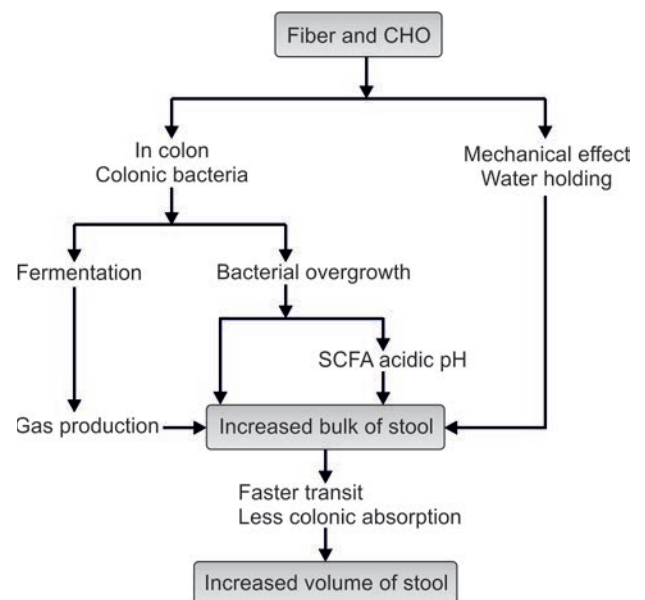

lactulose, lactitol, etc. in the dosage of 1-3 ml/kg body weight. These should always be given twice a day. Recently reported PEG for maintenance phase in the dose of 0.25 to 1g/kg/day has been shown to be very effective and safe even for long term use. The maintenance therapy has to continue for 6 months or even more depending upon the response. Routine use of bisacodyl, castor oil, senna and phenolphthalein is not recommended in children. These stimulate the peristalsis, active electrolyte transport and fluid movements.^{11,38-41}

Cisapride a prokinetic agent can be used in paraplegics, pseudo-obstruction, diabetics, chronic constipation, etc.⁴² Combination of various agents is effective to avoid recurrence of constipation. The most commonly used drugs/agents along with dosage and side effects are given in Table 8.

Dietary Modification

Encourage breastfeeding during early infancy and cereal supplementation should be started after 6 months of life. Diets rich in high fiber are bran based cereals, pulses, fruits, vegetables, etc. For older children and adults daily intake of 20 g of bran is quite effective to avoid constipation. In younger children the fiber requirement can be calculated as age in years plus 5. This gives the daily requirement of fiber in grams for that particular age (e.g. for 5 years + 5 = 10g).⁸ Intake of plenty of fluids is encouraged. Excess of drinks in form of milk, juices and cold drinks are to be avoided. Bakery products and junk foods to be discouraged.⁴³⁻⁴⁵ Mechanism by which dietary unabsorbed carbohydrates known as prebiotics increase the stool bulk is given in Flow chart 3.

Flow chart 3: Mechanism of action of fiber and carbohydrates

Retraining/Toilet Training

There should be positive reinforcement for toilet sitting and defecation. Toilet timing should be regular. Child should sit in squatting position for 5 to 10 minutes once or twice a day after the meals to take advantage of gastrocolic reflex. For proper sitting in the English type of latrines adequate foot rest should be provided to the children, so that the flexion of knee joints and hip joints is possible. Idea is to straighten the anorectal angle, so that stools can flow out easily. Positive reinforcement at home and by the physician is very important. Parents should be prepared to have verbal acclaim and selective awards for desired behavior, initiation of toileting, use of toilet, production of stool, acknowledging the cleaning after defecation and for repeated successes.⁵

Anal Fissure

In toddlers anal fissure is very important leading cause of retention and constipation. It should be taken care by giving sitz bath twice a day for two weeks. This will ensure the healing of the fissure. Xylocaine jelly as local application morning evening will help to provide relief of pain.

Biofeedback

Biofeedback is required when other measures are not working and there is anorectal dyssynergia. This helps in relaxation of external anal sphincter (EAS) and levator ani muscles. This is only possible above 5 years of age because cooperation of patient is very important. It is effective in 50 to 80 percent patients. Take the benefit of conditioning reflex in morning and evening like to move in front of toilet, to drink water, put the tap on and sitz bath. Multidisciplinary behavioral treatment is effective in chronic constipation and defecation process in children.^{9,46-49}

Follow-up

Long follow-up is required. In case the progress is very good the treatment can be weaned off after 6 months, but rest of the protocol in terms of high fiber diet and toilet training should continued for 2 to 3 years to avoid relapse. Appropriate psychiatric consultation should be taken when required. If there is atypical presentation or poor response pathological cause must be ruled out.⁵⁰

Outcome and Prognosis

Outcome with appropriate above mentioned therapeutic modalities is excellent in 45 to 100 percent of individuals. The quality of life and nutritional status improves significantly. Moderate response may be seen in 20 to 30 percent whereas 25-35 percent may have failure. Good prognostic indicators are better compliance, adequate intake of high roughage diet and self-confidence to

achieve the success. Poor prognostic indicators are hearing disabilities, disobedience, fearlessness, school time soiling, teen age occurrence, mental retardation, severe motor disability, associated disorders and neurogenic cause. In a recent study this has been shown that 30 percent of children suffering from constipation continue to be constipated during puberty. Recently reported systematic review articles on various aspects of chronic functional constipation have revealed that there is no evidence based treatment though use of PEG 3350 has been shown to be superior. The quality of life certainly improves with effective therapy.⁵¹⁻⁵⁷

Prevention

Prevention of colonic dysfunctions have received much less attention but attending pediatrician can play important role by providing anticipatory counseling in terms of appropriate feeding advise, high fiber diet, interpretation of normal bowel habits, counseling life issues of the child and early detection of problem and intervention.

SUMMARY

Constipation is a common problem in children and occurs more often in boys as compared to girls. Functional constipation occurs in 90 to 95 percent children whereas secondary causes are uncommon. In toddlers and school going children the anal fissure and painful act of defecation are important triggering factors to develop constipation. The low fiber diet in form of junk foods, soft beverages and bakery products have contributed lot in perpetuation of constipation. In case of functional chronic constipation there is no need to do many investigations. On examination detection of fecal mass per-abdomen or per-rectally is enough, at times plain X-ray abdomen may be required and will show impacted fecal matter and dilated rectum and colon. The acute constipation is simple and easy to treat. On the contrary the chronic constipation is usually associated with complications and is difficult to treat. The chronic constipation with impaction and encopresis requires evacuation followed by maintenance laxative therapy for 6 months in order to avoid further retention. The initial counseling, dietary advise to take fiber rich diet and toilet training are also very important components of treatment. The uncomplicated chronic constipation can be managed with maintenance therapy. The regular follow-up and adequate laxative treatment to ensure passage of soft stool without straining have key role in the success. After 6 months of rigorous drug therapy and the fiber rich diet, toilet training and reinforcement should continue for 2 to 3 years to avoid relapse of constipation later. The quality of life and growth and development improves significantly with meticulous multimodality approach.

Key Words: Constipation, acute or chronic, encopresis, definition and criteria, pathophysiology, impaction, approach, disimpaction, polyethylene glycol, enemas, lactulose, liquid paraffin, Hirschsprung's disease, fiber rich diet, biofeedback.

Diagnosis and Management of Gastroesophageal Reflux Disease

Manpreet Sethi, SK Mittal

Gastroesophageal reflux (GER) is defined as the passage of gastric contents into the esophagus with or without regurgitation and vomiting. GER is a normal physiological phenomenon and it occurs several times a day in healthy infants, children and adults. Most episodes of GER in healthy individuals last <3 minutes, occur in the postprandial period and cause few or no symptoms.¹ This is referred to as physiological GER. In contrast, gastroesophageal reflux disease (GERD) is said to be present when GER leads to troublesome symptoms and/or complications. Further, when there is an underlying anomaly such as hiatus hernia, short esophagus, etc. the GER is referred to as pathological reflux.

DIAGNOSIS OF GASTROESOPHAGEAL REFLUX DISEASE

History and Physical Examination

Gastroesophageal reflux (GER) or Gastroesophageal reflux disease (GERD) may present with a variety of symptoms and signs, which are not limited only to the gastrointestinal tract (Table 1).

Regurgitation, irritability, and vomiting are common in infants with physiologic GER or GERD² but are indistinguishable from regurgitation, irritability, and vomiting caused by food allergy, colic, and other disorders. Individual symptoms in children generally are not highly predictive of findings of GERD by objective studies. For example, in a study of irritable infants younger than 9 months of age, regurgitation >5 times per day had a sensitivity of 54 percent and specificity of 71 percent for a reflux index (RI) >10 percent by esophageal pH testing, whereas feeding difficulties, which are more difficult to define as an entity, had a sensitivity of 75 percent and specificity of 46 percent.³ Among older children, not all of the children with GER have heartburn or irritability. Conversely,

heartburn and irritability can be caused by conditions other than GER.

Some of the symptoms are more suggestive of underlying GERD. These include persistence of vomiting after 6 months of age, crying during or after feeds, neonatal

Table 1: Symptoms and signs that may be associated with gastroesophageal reflux

Gastrointestinal symptoms

1. Recurrent regurgitation with/without vomiting
2. Heartburn
3. Feeding difficulties
4. Ruminative behavior
5. Dysphagia
6. Hematemesis

Respiratory symptoms

1. Neonatal apneas
2. ALTE, e.g. SIDS
3. Recurrent aspiration pneumonias
4. Reactive airway disease/wheezing
5. Stridor
6. Hoarseness
7. Recurrent laryngitis/tracheitis (specially in post-TEF repair cases)
8. Chronic sinusitis

Neurological symptoms

1. Dystonic neck posturing (Sandifer's syndrome)

Others

1. Anemia
2. Failure to thrive
3. Dental erosions

Table 2: Warning signals in children with persistent vomiting warranting search for causes other than GER or complicated GERD

- Vomiting—bilious or blood stained
- Forceful or projectile vomiting
- Associated fever, diarrhea, lethargy, dehydration
- Abdominal distension, constipation, abdominal colics
- Associated dysphagia
- Failure to thrive
- Neurological s/s like seizures, micro/macrocephaly
- Developmental delay.

apnea in term infants, recurrent aspiration pneumonias, nonnocturnal, nonseasonal wheezing.

GERD should be suspected in infants and children with symptoms mentioned earlier; but none of the symptoms are specific to GERD alone; so the major role of history and physical examination in the evaluation of GERD is to rule out other and more worrisome disorders that present with vomiting (Table 2) and to identify complications of GERD such as esophageal stricture presenting as dysphagia.

Because individual symptoms do not consistently correlate with objective findings or response to medical treatment, parent- or patient-reported questionnaires based on clusters of symptoms have been developed to diagnose GERD. Orenstein et al⁴ developed a diagnostic questionnaire for GERD in infants. A score of >7 (of 25 possible) on the initial instrument demonstrated a sensitivity of 0.74 and specificity of 0.94 during primary validation. However, when applied to a population in India, it had a sensitivity and specificity of only 43 percent and 79 percent, respectively, compared with pH-monitoring results.⁵

A 5-item questionnaire developed for children 7 to 16 years of age had a sensitivity of 75 percent and a specificity of 96 percent compared with pH monitoring during primary validation.⁶

A simplified approach to diagnosis of GERD based on symptoms and signs has been suggested and is given in Flow charts 1 and 2.

Diagnostic Tests for GERD

A variety of diagnostic tests are available (Table 3). None of them is hundred percent reliable, nor applicable in all circumstances. Clinicians must use their discretion while ordering these tests.

The diagnosis of GERD is inferred when tests show excessive frequency or duration of reflux events, esophagitis, or a clear association of symptoms and signs with reflux events, in the absence of alternative diagnoses. Although many tests have been used to diagnose GERD, few studies compare their utility. Importantly, it is not known whether tests can predict an individual patient's response to therapy. Tests are useful to document the presence of pathologic reflux or its complications, to establish

Table 3: Diagnostic tests available for GER/GERD

1. Upper GI barium studies
2. Esophageal and gastric ultrasonography
3. Nuclear scintigraphy (milk scan)
4. Esophagoduodenoscopy and biopsy
5. Esophageal 24 hr pH monitoring
6. Esophageal motility studies
7. Esophageal impedance
8. Therapeutic trial.

a causal relation between reflux and symptoms, to evaluate therapy, and to exclude other conditions. Because no test can address all of these questions, tests must be carefully selected according to the information sought, and the limitations of each test must be recognized.

Barium Contrast Radiography

Although simple and easily available, the upper GI series is neither sensitive nor specific for diagnosing GERD. The sensitivity, specificity and positive predictive values range from 29 percent to 86 percent, 21 percent to 83 percent, and 80 percent to 82 percent respectively when compared with esophageal pH monitoring.^{7,8} The brief duration of the upper GI series produces false negative results whereas the frequent occurrence of nonpathological reflux during the test produces false positive results. It involves radiation hence, is not a preferred test. However, the upper GI series is useful in settings where anatomical abnormalities like strictures, hiatus hernia, achalasia, tracheoesophageal fistula, intestinal malrotation or pyloric stenosis are suspected as part of the differential diagnosis of infants and children with persistent vomiting.

Esophageal and Gastric Ultrasonography

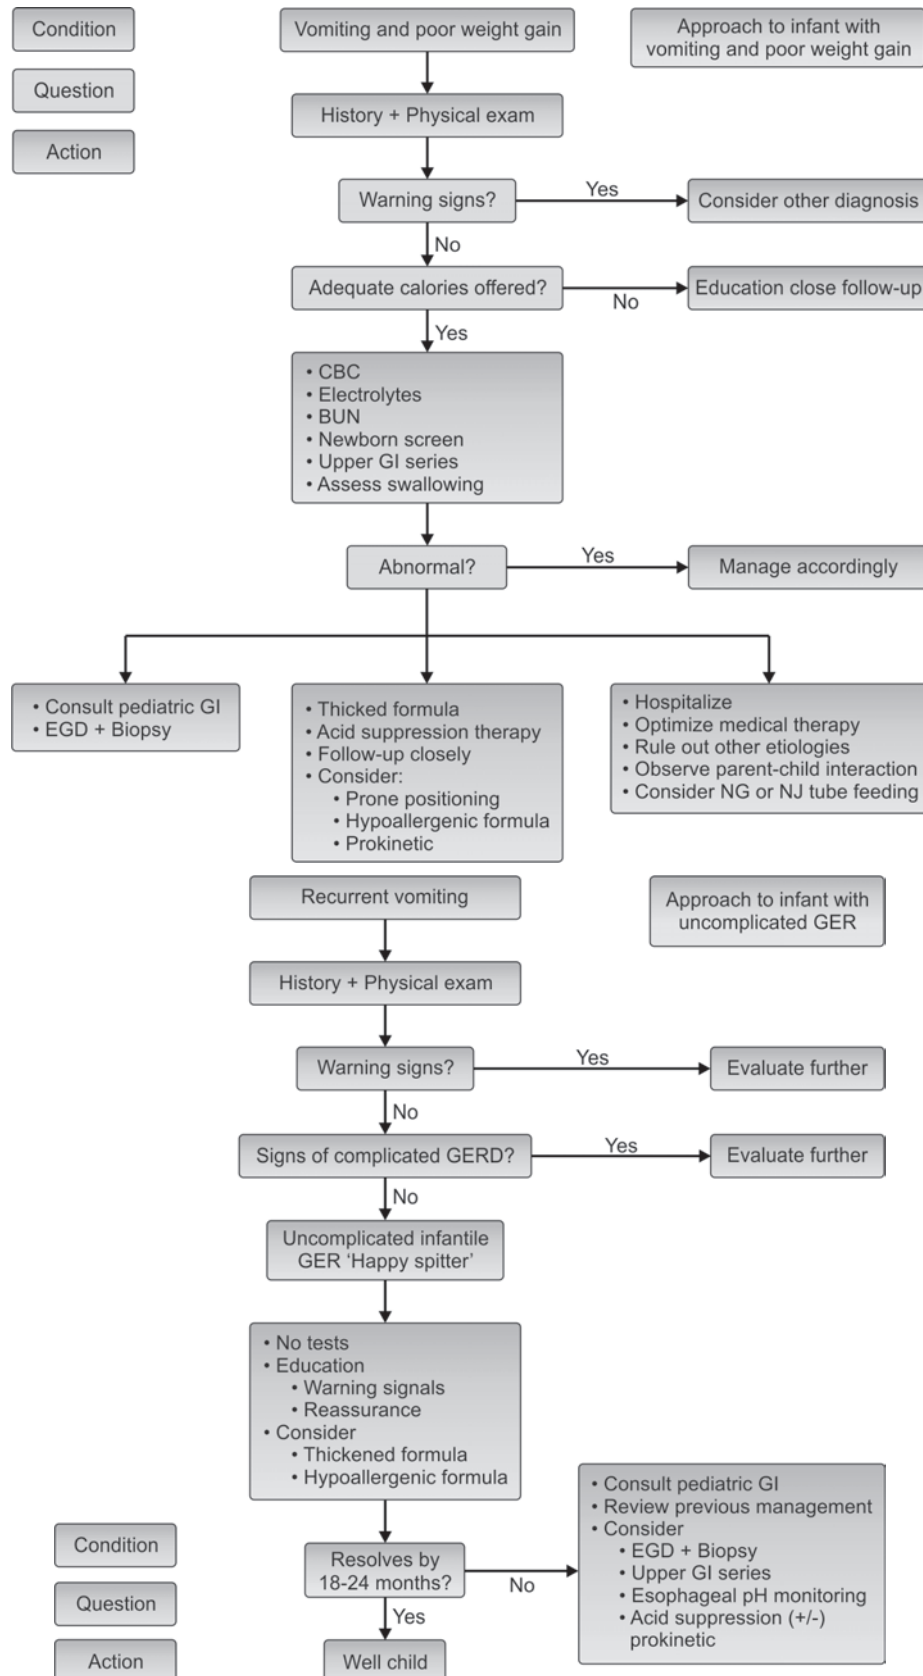

Ultrasonography is not recommended as a test for GERD but can provide information not available through other technology. Ultrasonography of the gastroesophageal junction can detect fluid movements over short periods of time and thereby can detect nonacid reflux events. It can also detect hiatus hernia, length and position of the LES relative to the diaphragm, and magnitude of the gastroesophageal angle of His. Barium upper GI series can also provide the same information. When compared with the results of 24-hour esophageal pH testing as a diagnostic test for GERD, the sensitivity of color Doppler ultrasound performed for 15 minutes postprandial is about 95 percent with a specificity of only 11 percent, and there is no correlation between reflux frequency detected by ultrasound and reflux index detected by pH monitoring.⁹

Nuclear Scintigraphy (Milk Scan)

In gastroesophageal scintigraphy, food or formula labeled with 99technetium is introduced into the stomach and

Flow chart 1: Simplified approach to diagnosis of GERD based on symptoms and signs

[(Adapted from Joint Recommendations of the North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition (NASPGHAN) and the European Society for Pediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) 2009)]

areas of interest—stomach, esophagus, and lungs are scanned for evidence of reflux and aspiration. The nuclear scan evaluates only postprandial reflux and demonstrates reflux independent of the gastric pH. While performing the test it is important to remember that the amount of milk/formula to be given must be roughly equal to the amount of the normal feed for that infant and to wait for about half an hour before scanning the baby. The advantages of this technique are that it demonstrates both acidic and nonacidic reflux, can evaluate gastric emptying (which may be delayed in children with GERD), and may even demonstrate aspirations. Moreover, it is noninvasive and radiation free. However, lack of standardized techniques and the absence of age-specific norms limit the value of this test. Sensitivity and specificity of a 1-hour scintigraphy for the diagnosis of GERD are 15 percent to 59 percent and 83 percent to 100 percent, respectively, when compared with 24 hour esophageal pH monitoring.^{10,11} Late postprandial acid exposure detected by pH monitoring may be missed with scintigraphy. Gastroesophageal scintigraphy scanning can detect reflux episodes and aspiration occurring during or shortly after meals, but its reported sensitivity for microaspiration is relatively low. Evidence of pulmonary aspiration may be detected during a 1-hour scintigraphic study or on images obtained up to 24 hours after administration of the radionuclide. A negative test does not exclude the possibility of infrequently occurring aspiration. Gastric emptying studies have shown prolonged half emptying times in children with GER. Delayed gastric emptying may predispose to GERD. Tests of gastric emptying are not a part of the routine examination of patients with suspected GERD, but may be important when symptoms suggest gastric retention. Despite its limitations, this can be useful test in infants, provided it is done and interpreted properly.

Endoscopy and Biopsy

The role of endoscopy and biopsy in the evaluation of GERD is primarily to demonstrate the effects of GERD on the esophagus in the form of reflux esophagitis and not to demonstrate or document reflux directly. It therefore, has limited application in the diagnosis of GERD. The main indications for endoscopy and biopsy are situations where the complication of reflux esophagitis is suspected, such as older children with recurrent abdominal pain, heartburn and chest pain or infants and younger children with alarm symptoms like irritability, crying excessively during feeds, unexplained anemia, failure to thrive, etc. It is also useful in evaluating empiric therapy failure, for preoperative evaluation and to rule out other conditions in the differential diagnosis such as eosinophilic or infective esophagitis, Crohn's disease, Barrett's esophagus, etc.¹² It is not useful in infants younger than 6 to 9 months of age.

Recent global consensus guidelines define reflux (erosive) esophagitis as the presence of endoscopically visible

breaks in the esophageal mucosa at or immediately above the gastroesophageal junction.¹² Mucosal erythema or an irregular Z-line is not a reliable sign of reflux esophagitis. Grading the severity of esophagitis, using a recognized endoscopic classification system, is useful for evaluation of the severity of esophagitis and response to treatment.¹³ The presence of endoscopically normal esophageal mucosa does not exclude a diagnosis of nonerosive reflux disease (NERD) or esophagitis of other etiologies.¹⁴ Histology may be normal or abnormal in NERD because GERD is an inherently patchy disease.¹⁴ Therefore, multiple biopsies must be obtained to exclude reflux esophagitis. Histological findings of eosinophilia, elongation of papillae, basal hyperplasia, and dilated intercellular spaces (spongiosis) are usually suggestive of reflux esophagitis, although not very specific of this condition.¹⁴ Taken with multiple esophageal biopsies, endoscopy provides more than 80 percent sensitivity and specificity for the diagnosis of reflux disease.

When biopsies from esophageal mucosa show columnar epithelium, the term Barrett's esophagitis should be applied and the presence or absence of intestinal metaplasia specified.^{14,15} BE occurs with greatest frequency in children with underlying conditions putting them at high risk for GERD. The primary role for esophageal histology is to rule out other conditions in the differential diagnosis, such as eosinophilic esophagitis, Crohn's disease, Barrett's esophagus, and infection.

Esophageal pH Monitoring

Intraluminal esophageal pH monitoring measures the frequency and duration of acid esophageal reflux episodes. Although not hundred percent reliable, it is considered the 'gold standard' for the diagnosis of GER. It only demonstrates GER and not necessarily GERD unless the reflux symptoms are correlated with acid reflux episodes with the help of symptom diary.

Most commercially available systems include a catheter for nasal insertion with one or more pH electrodes (antimony, glass, or ion-sensitive field effect) arrayed along its length and a system for data capture, analysis, and reporting. The recording device is a small box with high portability and allows maximum normal activity. Prokinetic agents should be discontinued at least 48 hours before, H-2 antagonist at least 3 to 4 days and antacids at least 24 hours before the investigation. Calibration is done before the procedure. For standard recording, the pH electrode is placed in adults, 5 cm above the lower esophageal sphincter under fluoroscopy. In children it may be placed about 3 to 5 cm above GE junction and the position be checked with a plain X-ray chest. The location of the tip of the probe should be at the third vertebra above the diaphragm. Patients are allowed normal diet and unrestricted activity for a 24 hr recording period. Parents are instructed to record activities and events like

eating, drinking, change of position and occurrence of symptoms and a symptom/activity diary is maintained. Data is collected in the recorder for 24 hours, then downloaded into a computer and finally graphic and numerical displays can be presented. It must be noted here that it is important to actually see the record to ensure absence of artifacts and to correlate with symptom diary. Only those episodes are relevant which are associated with occurrence of symptoms. Recordings of less than 24 hours are not that helpful.

Interpretation of 24 hours esophageal pH monitoring

- A pH of 4 is regarded as the cut-off level for acid GER

The standard parameters calculated are:

- Total number of episodes with a pH <4
- No. of episodes lasting >5 minute with a pH <4.0
- Percentage of time related to the total duration of the investigation with a pH <4 (reflux index).

In pH studies conducted with antimony electrodes, a RI >7 percent is considered abnormal, a RI <3 percent is considered normal, and a RI between 3 percent and 7 percent is indeterminate.^{1,16} In infants up to 18 months of age an RI of >10 is taken as abnormal.

The sensitivity and specificity is quoted as 87 to 93 percent and 93 to 97 percent respectively. In adult group of patients, the reproducibility of the test varies from 77 to 85 percent.^{17,18} It does not detect alkaline reflux.

The advantages of esophageal pH monitoring are that it detects episodes of acid reflux, determines association of acidic GER with symptoms, can assess the adequacy of anti-secretory treatment and helps to select those children with wheezing or respiratory symptoms in which acid reflux may be an aggravating factor. However, its disadvantages include nondetection of nonacidic or weakly acidic reflux episodes. In children with documented esophagitis, normal esophageal pH monitoring suggests a diagnosis other than GERD.

Wireless capsule pH monitoring is a relatively new modification of the conventional pH probe. It offers the advantage of being more patient friendly with greater comfort in carrying out daily activities. Moreover, it allows for a longer, 48 hours period recording.¹⁹ However, its limitations include an endoscopic placement, greater cost and variability in the records obtained on day1 and day 2.

Double lumen esophageal pH monitoring (where one port is placed higher—near the upper esophageal sphincter) allows demonstration of high reflux and is useful in correlating upper respiratory symptoms with Gastroesophageal reflux.

Motility Studies

Esophageal manometry measures esophageal peristalsis, upper and lower esophageal sphincter pressures, and the coordinated function of these structures during

swallowing. Although esophageal manometry has been an important tool in studying the mechanisms of GERD but GERD cannot be diagnosed by esophageal manometry. Manometric studies were critical in identifying TLESR (transient relaxation of lower esophageal sphincter) as a causative mechanism for GERD. Recent studies indicate that there is no role for manometry in predicting outcome of fundoplication. Manometric studies are also important in confirming a diagnosis of achalasia or other motor disorders of the esophagus that may mimic GERD. Esophageal manometry may be abnormal in patients with GERD, but the findings are not sufficiently sensitive or specific to confirm a diagnosis of GERD, nor to predict response to medical or surgical therapy. It may be useful in patients who have failed acid suppression and who have negative endoscopy to search for a possible motility disorder, or to determine the position of the LES to place a pH probe. It is also useful before planning a fundoplication.

Combined Multiple Intraluminal Impedance (MII) and pH Monitoring

Multiple intraluminal impedance (MII) is a relatively new procedure in which esophageal impedance tracings are analyzed for the typical changes in impedance caused by the passage of liquid, solid, gas, or mixed boluses. If the impedance changes of a liquid bolus appear first in the distal channels and proceed sequentially to the proximal channels, they indicate retrograde bolus movement, which is GER. The upward extent of the bolus and the physical length of the bolus can also be evaluated.²⁰ MII can detect extremely small bolus volumes.

MII and pH electrodes can and should be combined on a single catheter. The combined measurement of pH and impedance (pH/MII) provides additional information as to whether refluxed material is acidic, weakly acidic, or nonacidic. Evaluation of MII recordings is aided by automated analysis tools. Normal values for all of the age groups have not yet been established. The combination of pH/MII with simultaneous monitoring of symptoms using video-polysomnography or manometry has proven useful for the evaluation of symptom correlations between reflux episodes and apnea, cough, other respiratory symptoms, and behavioral symptoms.²¹ The technology is especially useful in the postprandial period or at other times when gastric contents are nonacidic.

Tests on Ear, Lung and Esophageal Fluids

Finding of lipid-laden macrophages in bronchoscopically obtained alveolar aspirate (BAL) suggests aspiration of gastric contents and can be related to presence of GERD.

Recent studies have suggested that finding pepsin, a gastric enzyme, in middle ear effusions of children with chronic otitis media, indicates that reflux is playing an etiologic role.²² However, this relation has not been validated in controlled treatment trials.

Empiric Trial of Acid Suppression as a Diagnostic Test

In adults, empiric treatment with acid suppression (usually with proton pump inhibitors like Omeprazole), without diagnostic testing, has been used for symptoms of heartburn, chronic cough, noncardiac chest pain, and dyspepsia. However, empiric therapy has only modest sensitivity and specificity as a diagnostic test for GERD, depending upon the comparative reference standard used (endoscopy, pH monitoring, symptom questionnaires),²³ and the appropriate duration of a “diagnostic trial” of acid suppression has not been determined. The 2-week “PPI test” lacks adequate specificity and sensitivity for use in clinical practice. In an older child or adolescent with symptoms suggesting GERD, an empiric PPI trial is justified for up to 4 weeks. Improvement following treatment does not confirm a diagnosis of GERD because symptoms may improve spontaneously or respond by a placebo effect.

When to Perform Diagnostic Tests

There is no unanimity on the indications for undertaking diagnostic evaluations for suspected GERD. In general, infants with just regurgitations or vomiting and continuing to gain weight do not need any investigations unless danger signs are present as mentioned earlier. Generally agreed indications for undertaking diagnostic evaluation for GERD are mentioned in Table 4.

Generally, in children younger than 2 years, the indications for work up/investigations for GER include situations where complications of GERD are suspected clinically. These may include a generally unhappy baby, irritability during and after feeds, persistent vomiting, recurrent pneumonias, chronic cough, or a child who is failing to thrive.

Similarly, in children older than 2 years, there are certain features that may warrant investigations for GER. These include persistence of vomiting since the child was less than 2 years, new onset vomiting, or heartburn not responsive to 4 weeks of medical therapy. Investigations are also called for in cases where there is a suspicion of complications of GER such as undiagnosed anemia, dysphagia, odynophagia, recurrent pneumonias and nonseasonal asthma.

Which Test to Perform?

It is advisable in such a scenario, to allow clinical presentation to dictate the diagnostic approach. For instance, in case of persistent vomiting or dysphagia, anatomical causes or severe esophagitis are to be investigated, preferably through barium studies and EGD. Alternatively, if the clinical presentation is in the form of wheezing, apnea, or recurrent pneumonia, investigation into such being secondary to reflux are advisable, with pH monitoring and nuclear scans. If seizure like activities are observed, especially with normal EEGs, it may be advisable to investigate the factum of reflux with pH monitoring and videographic recording. Lastly, if the presentation is of a feeding problem with a persistent failure to thrive, or persistent or recurrent anemia, reflux esophagitis should be investigated through an EGD along with biopsy.

Evaluation of Children with Recurrent Respiratory Symptoms and Suspected GER

Some of the children with chronic, persistent asthma may have an underlying GER and may benefit from therapy aimed to decrease acid reflux. However, as only a small number of asthmatic children benefit from GER therapy, it is important to carefully select patients for GERD evaluation and management (Flow chart 2).

While investigating possible causes of recurrent pneumonia and suspected GER, it is advisable to exclude other potential causes, such as anatomical abnormality, aspiration during swallowing, foreign body, cystic fibrosis or immunodeficiency, neurological impairments, etc. Tests useful in differentiating cases of recurrent pneumonia and suspected GER with these others, include flexible bronchoscopy with BAL for lipid-laden alveolar macrophages, nuclear scintigraphy, VSS (video fluoroscopic swallowing study), or FEEST (flexible endoscopic evaluation of swallowing with sensory testing), the latter two being useful for effectively evaluating airway protective mechanisms.

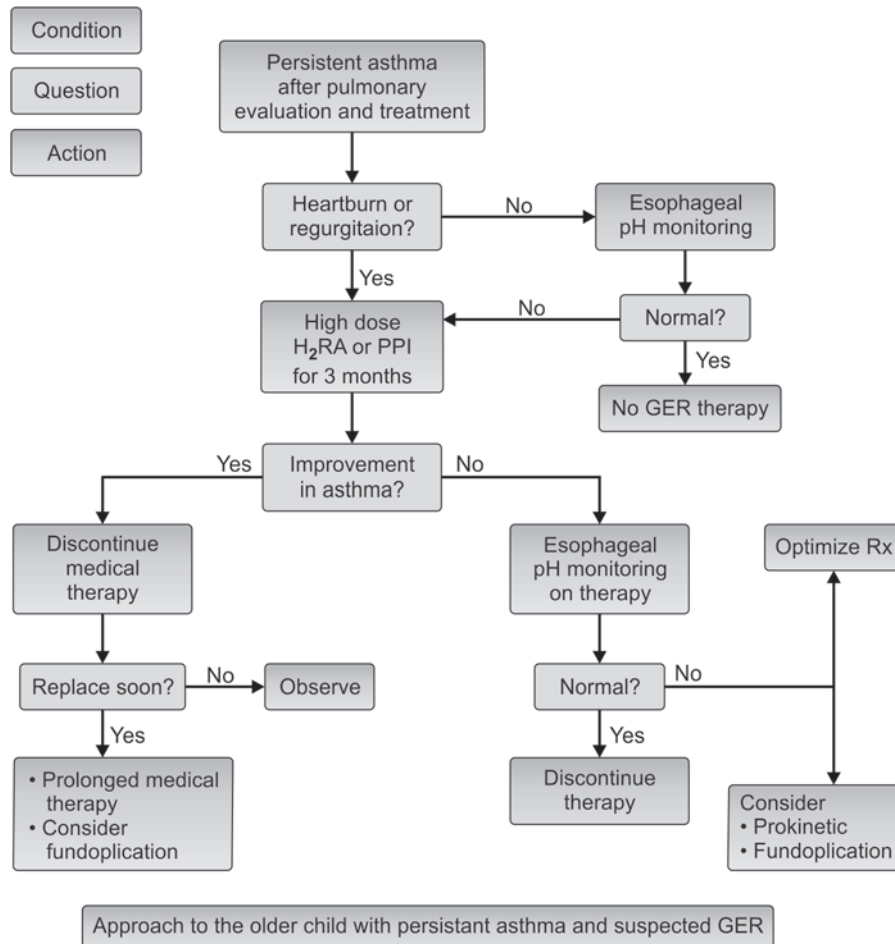

Management of (Physiological) GER

Regurgitation or vomiting of feeds is very common in infants being present in more than 70 percent infants. It reaches its peak at about 3 to 4 months of age and then gradually declines. This does not affect the health of infants and apart from causing nuisance to mother it causes no harm to the infant. As such therefore, it does not require any specific treatment/management. Mothers need to be reassured and the infant followed up for adequate weight gain. Advice regarding burping should be given and may help in decreasing visible vomiting.

However, if the mother is really concerned then non-pharmacological methods of management can be tried. These include changes in posture and thickening of feeds.

Table 4: Indications for undertaking diagnostic evaluation for GERD

- Uncertain diagnosis
- Atypical symptoms
- Symptoms associated with complications
- Inadequate response to therapy
- Recurrent symptoms
- Prior to anti-reflux surgery

Flow chart 2: Simplified approach to diagnosis in an older child with asthma and suspected to have GER

Positioning Therapy for Infants

Several studies in infants have demonstrated significantly decreased acid reflux in the flat prone position compared with flat supine position.^{24,25} However, there are significant concerns regarding the association of SIDS with the prone position and therefore, prone position is recommended only in the awake infant who can easily be observed and specially in the postprandial period. During sleep, only the supine position is recommended unless the infant has certain upper airway disorders where the risk of death from GERD may outweigh the risk from SIDS.

Also, to be noted is the fact that the amount of reflux in supine infants with head elevated is equal to or greater than in infants supine and flat.^{24,25}

The semi-supine positioning as attained in an infant car seat exacerbates GER.²⁴ Although the full upright position appears to decrease measured reflux, one study suggested that using formula thickened with rice cereal is more effective in decreasing the frequency of regurgitation than upright positioning after feeds.²⁶

In older children, the left lateral position with head high is considered effective and better than the supine position for the management of reflux.

Feeding Changes in Infants

Breast-fed and formula-fed infants have a similar frequency of physiologic GER, although the duration of reflux episodes measured by pH probe may be shorter in breast-fed infants. In any case, most breast-fed infants can be safely managed on advise to be burped adequately, if required, to be done also in the middle of feeding in addition to be done at the end of feeding and before returning the baby to the bed. Physiological GER should never become an indication to change to formula feeding.

Top fed infants with physiological GER, may benefit with thickening of feeds. Rice cereal is a good thickening agent. Adding thickening agents such as rice cereal to formula does not decrease the time with pH < 4 (reflux index) measured by esophageal pH studies, but it does decrease the frequency of overt regurgitation.^{27,28} Rice cereal is the most commonly used thickening agent for formula. Thickening a 20-kcal/oz infant formula with 1 tablespoon of rice cereal per ounce increases the energy density to ~34 kcal/oz (~1.1 kcal/mL). Thickening with 1 tablespoon per 2 oz of formula increases the energy density to ~27 kcal/oz (~0.95 kcal/mL). Although the actual number of esophageal reflux episodes may not decrease, the reduction in

regurgitation may be a welcome improvement in quality of life for caregivers.

A subset of top fed infants with allergy to cow's milk protein experience regurgitation and vomiting indistinguishable from that associated with physiologic GER. In these infants, vomiting frequency decreases significantly (usually within 2 weeks) after the elimination of cow's milk protein from the diet, and reintroduction causes recurrence of symptoms. Breast-fed infants with regurgitation and vomiting may benefit from a trial of withdrawal of cow's milk and eggs from the maternal diet.

Lifestyle Changes in Children and Adolescents

Current evidence generally does not support (or refute) the use of specific dietary changes to treat reflux beyond infancy. Expert opinion suggests that children and adolescents with GERD should avoid caffeine, chocolate, alcohol, and spicy foods if they provoke symptoms. In an overweight individual, weight loss does decrease reflux, and is therefore recommended. Smoking should be avoided in those with GERD because it has been linked to adenocarcinoma of the esophagus in adults. Some studies have shown that chewing sugarless gum after a meal decreases reflux.²⁹

Pharmacologic Therapies

Prokinetics

Prokinetics are a group of drugs, which decrease esophageal motility, increase LES pressure and increase gastric emptying. Thus, they counter the pathophysiological mechanisms of reflux. Although a number of prokinetic agents are available in the market, none of them has been proven to be effective and safe.

Available prokinetic agents include dopamine receptor blockers (Metoclopramide, Domperidone); serotonin receptor (5HT₃,4) agonists (Cisapride, Mosapride), and drugs with both effects (Itopride).

Domperidone and metoclopramide are antidopaminergic agents that facilitate gastric emptying and also increase the LES tone. However, no RCT is available to demonstrate their clinical efficacy in children with GERD. They are poorly active and are associated with side effects like lethargy, irritability, gynecomastia, galactorrhea, and extrapyramidal reactions. They may be used for short-term but their long-term use is therefore not recommended.

Cisapride is a mixed serotonergic agent that facilitates the release of acetylcholine at synapses in the myenteric plexus, thus increasing gastric emptying and improving esophageal and intestinal peristalsis. Clinical studies of cisapride in children with GERD showed significant reduction in the RI but with less consistent reduction in symptoms.³⁰ However, cisapride was found to produce prolongation of the QTc interval on electrocardiogram, a finding increasing the risk of sudden death, its use has

become restricted. Moreover, it is not recommended to be used along with some other drugs like macrolides, antifungals, and antivirals that are also metabolized through cytochrome P450. Mosapride on the other hand has a better safety profile (than cisapride) vis a vis cardiac arrhythmias and shows no interaction with other cytochrome P 450 inhibitors like macrolids, antifungals, antivirals, etc. Although used commonly in adults, its dose and use in children is not yet clearly defined. Also no RCT is yet available regarding its efficacy and safety in children.

Other prokinetic drugs like bethanechol³¹ (a direct cholinergic agonist), erythromycin (a dopamine receptor antagonist) have uncertain efficacy and a high incidence of side effects limiting their use in clinical practice.³³

Baclofen, a γ -amino-butyric-acid receptor agonist, reduces both acidic and nonacidic reflux and also increases gastric emptying in children. However, it has unacceptable side effects like drowsiness, dizziness, fatigue and lowers seizure threshold that preclude its routine use.¹

Histamine-2 Receptor Antagonists (H2RA)

Histamine-2 receptor antagonists (H2RAs) decrease acid secretion by inhibiting histamine-2 receptors on gastric parietal cells. Gastric pH begins to increase within 30 minutes of administration and the effect lasts for 6 hours. Tachyphylaxis or diminution of the response has been observed after 6 weeks of administration of H2RA drugs, hence their long-term use is not recommended. Also, the efficacy of H2RA in achieving mucosal healing is greater in mild esophagitis than in severe esophagitis. It is therefore, suggested that H2RA maybe used in older children and adolescents for the treatment of GERD symptoms and for healing esophagitis although H2RA are less effective than PPI for both symptom relief and healing of esophagitis.³²

Side effects of H2RA in infants include irritability, head banging, headache, and somnolence. The commonly used H2RA include Ranitidine, Famotidine, Cimetidine and Nizatidine. The usual dose of Ranitidine is 2 mg/kg/day in 2 divided doses.

Proton Pump Inhibitors

Proton pump inhibitors (PPIs) inhibit acid secretion by blocking Na⁺-K⁺-ATPase, the final common pathway of parietal cell acid secretion, often called the proton pump. The superior efficacy of PPIs is largely because of their ability to maintain intragastric pH at or above 4 for longer periods and to inhibit meal-induced acid secretion, a characteristic not shared by H2RAs. In contrast with H2RAs, the effect of PPIs does not diminish with chronic use. The potent suppression of acid secretion by PPIs also results in decrease of 24-hour intragastric volumes, thereby facilitating gastric emptying and decreasing volume reflux.^{32,33} Side effects of PPIs include constipation, diarrhea, dizziness, headache and their long-term use may be associated with side effects of acid

suppression like malabsorption of nutrients and drugs and microbial overgrowth.

PPIs currently approved for use in children are omeprazole, lansoprazole, and esomeprazole. No PPI has been approved for use in infants younger than 1 year of age. The dose of omeprazole is 1 to 3.3 mg/kg/day given once or divided twice a day. That of lansoprazole is 1.4 mg/kg/day OD. In clinical trials they have proved to be equally efficacious. Ease of administration of lansoprazole in young children, with the availability of easily dissolvable tablets makes it a preferred drug for them.

Other Agents

Antacids directly buffer gastric contents, thereby reducing heartburn and healing esophagitis. On-demand use of antacids may provide rapid symptom relief in some children and adolescents with NERD. Although, this approach appears to carry little risk, long-term use of antacids containing aluminum hydroxide is associated with side effects like increased plasma aluminum levels and those containing calcium carbonate with milk alkali syndrome (a triad of hypercalcemia, alkalosis and renal failure). Moreover, these agents have a short duration of action and need to be given 3 to 4 times a day. These agents therefore, have limited use and are beneficial only for immediate relief in older children and adolescents on a need basis. Their routine or long-term use in the management of GERD is not recommended.¹

Surface protective agents mostly comprise of alginate or sucralfate. Alginates are insoluble salts of alginic acid, a component of algal cell walls. Sucralfate is a compound of sucrose, sulfate, and aluminum, which, in an acid environment, forms a gel that binds to the exposed mucosa of peptic erosions. Although these agents have shown to be effective in decreasing symptoms and healing of nonerosive esophagitis in adults, the available data of their safety and efficacy in children is inadequate to warrant their routine use in the management of GERD in children.

Supplementary Feedings

Infants with GERD who are unable to gain weight despite conservative measures (and pharmacological treatment) and in whom nasogastric or nasojejunal feeding may be beneficial are rare. Similarly, nasojejunal feeding is occasionally useful in infants with recurrent reflux-related pneumonia to prevent recurrent aspiration.

SURGICAL THERAPY

Fundoplication decreases reflux by increasing the LES baseline pressure, decreasing the number of TLESRs and the nadir pressure during swallow-induced relaxation, increasing the length of the esophagus that is intra-abdominal, accentuating the angle of His, and reducing an HH if present.³⁴ Fundoplication usually eliminates

reflux, including physiologic reflux. Fundoplication does not correct underlying esophageal clearance, gastric emptying, or other GI dysmotility disorders.¹

Surgical treatment of gastroesophageal reflux should be considered for the following patients:

- Infants and children who have failed medical therapy for gastroesophageal reflux (typically over 12 week) and those who cannot be weaned off of acid-reducing medications
- Those with an atypical presentation, especially respiratory, whose symptoms are clearly associated with gastroesophageal reflux (e.g. obstructive apnea temporally associated with reflux during pH monitoring. However, a period of medical therapy (including acid blockade) under close monitoring conditions should be attempted in many cases prior to recommending a surgical approach
- Patients with complications of gastroesophageal reflux, such as aspiration, stricture of the esophagus, or Barrett esophagus should be considered for surgical treatment
- Patients with neurologic impairment that requires feeding gastrostomy who are found to have pathologic reflux and remain medication dependent should also be considered for surgery.
- Patients with chronic reflux and recurrence of anastomotic stricture after repair of esophageal atresia should be considered for surgical treatment.

A large open RCT compared the efficacy and safety of laparoscopic fundoplication versus esomeprazole (20 mg q.i.d) for treatment of adults with GERD.³⁵ Short-term outcomes were reported in an interim analysis of data at 3 years. More than 90 percent of both the surgically and medically treated adults showed good to excellent symptom control; 10 percent of the surgical group had dysphagia whereas dysphagia was uncommon in the medically treated group. Quality of life measures were similar in both groups.³⁵

SUMMARY

While gastroesophageal reflux is very common in infants in first 6 months of life, in most it is self-limiting. At this age it is important to consider and exclude other, more ominous, causes of vomiting. Infants with GER, who continue to gain weight adequately, require no investigations or management. Diagnosis of GERD is essentially clinical, based on high index of suspicion and careful analysis of myriad of signs and symptoms present in the child. Investigative modality should be carefully selected depending on the age of the child and type of symptom complex. Medical management with prokinetics and or acid suppression therapy is helpful in most of the cases. PPIs are the most useful acid suppression drugs which can be used over a long period of time safely. Surgery is rarely required unless there is an underlying anatomical abnormality.

Pediatric Liver Transplantation

Nishant Wadhwa

INTRODUCTION

Liver transplantation (LT) has been very successful in treating children with end-stage liver disease, and offers the opportunity for a long-term healthy life. The survival rates have improved significantly over the last decade mainly due to the advances made in the surgical techniques, better postoperative care and newer immunosuppressive drugs.¹ The improved results have also led to an increasing awareness of this treatment modality in the developing world with successful LT having been reported in both adults and children from various centers across India. The history of pediatric liver transplantation across the globe has clearly shown that success is dependent on strict and integrated collaboration between referring pediatricians, pediatric transplant hepatologists, transplant surgeons, nurses, transplant coordinators, psychologists and social workers.

INDICATIONS

The main indications for LT are listed in Table 1. Biliary atresia constitutes the most common indication for LT in the pediatric age group world over.² Most of these infants usually have undergone a Kasai's procedure, which has failed or have been diagnosed late in the course of the disease when cirrhosis has already set in, thus requiring a transplant as a primary procedure. In conditions such as Bile duct paucity, progressive familial intrahepatic cholestasis, LT is indicated to eliminate severe debilitating symptoms such as pruritis and associated failure to thrive and poor quality of life. Children affected with these diseases are also at a higher risk of developing liver carcinoma.³

Metabolic diseases are the second most common indication for LT. These are divided in two groups depending on the presence or absence of structural damage to

the liver. In the first group are diseases such as Wilson's disease, tyrosinemia, which have a potential to progress to end stage liver failure and acute liver failure. Diseases such as Crigler-Najjar syndrome-I, ornithine transcarbamylase (OTC) deficiency, LT helps restore the deficiency of single enzyme leading to normal life expectancy. In Primary hyperoxaluria type-I, combined liver and kidney transplantation is considered when irreversible kidney damage from oxalic acid accumulation has developed.^{4,5} While liver transplantation has been suggested for organic acidemia, LT in these diseases does not correct the enzyme deficiency in other organs besides liver. Although the quality of life is improved, the patients remain at risk of severe extrahepatic disease complications.⁶

Children in acute liver failure (ALF) constitute an important subgroup who benefit immensely with a LT. There are specific criteria laid down for identifying children with ALF in whom survival is unlikely without LT (Tables 2 and 3). There are separate criteria for Acetaminophen induced liver failure and nonacetaminophen induced cases.⁷ The positive predictive value of these criteria in predicting mortality in the absence of LT has been 70 to 100 percent in various studies.

Hepatoblastoma is the most common liver tumor in children and, when nonresectable, is an indication for total hepatectomy and liver transplantation. Children with hepatoblastoma are initially treated with chemotherapy and then evaluated for resection or transplantation. Hepatocellular carcinoma in children is rare and is often secondary to congenital liver disease. The development of hepatocellular carcinoma has been reported in biliary atresia, Alagille's syndrome, progressive intrahepatic cholestasis. In children with tyrosinemia, there is a 33 percent incidence of hepatocellular carcinoma before 2 years of age.

CONTRAINDICATIONS

The following are the contraindications to LT in children:

- Nonresectable extrahepatic malignant tumor
- Concomitant end-stage organ failure that cannot be corrected by a combined transplant
- Uncontrolled sepsis
- Irreversible serious neurological damage.

PRETRANSPLANT EVALUATION

The primary goal of the evaluation process is to identify appropriate candidates for liver transplantation and to establish a pretransplantation plan. Liver transplantation is a life saving procedure and is opted for in a situation when all other modes of therapy are redundant and found ineffective. Hence, a thorough assessment prior to a transplant is a must. The aim of this assessment is:

- To confirm the diagnosis and severity of disease
- To define the patients general medical status
- To determine eligibility and priority for transplant
- To exclude contraindications to transplantation
- To identify active infections and assess the immunological status of the child
- To rule out cardiac malformations that might need to be corrected before transplantation
- To arrange interim supportive care
- To establish a pretransplant therapeutic plan: immunizations, when possible, nutritional support to optimize growth, dental care.

Table 1: Indications for LT in children

Extrahepatic cholestasis	Biliary atresia
Intrahepatic cholestasis	Nonsyndromic bile duct paucity
	Progressive intrahepatic cholestasis (PFIC)
	Syndromic bile duct paucity (Alagille's syndrome)
Metabolic diseases	Wilsong's disease
	Tyrosinemia
	Inborn errors of bile acid metabolism
	Disorders of urea cycle
	Primary hyperoxaluria type-I
	Organic acidemia
	Disorders of carbohydrate metabolism
	Crigler-Najjar syndrome type-I
Acute liver failure	
Others	Primary liver tumor
	Cystic fibrosis

- To inform parents about the transplantation procedure and on the post-transplantation period in order to motivate and prepare them to accept and deal with all issues and possible complications of the procedure.
- To assess the socioeconomic and educational status of the family and evaluate logistic issues.

Hepatic function is assessed by measurement of albumin and prothrombin time (synthetic function) and bilirubin, transaminases, alkaline phosphatase and gamma-glutamyl transpeptidase. Doppler ultrasonography and/or MR or conventional angiography is used to delineate the vascular anatomy. A nutritional, developmental, cardiac and dental assessment is performed in all children. Serological examination is performed to document immunity to viral pathogens, important ones being CMV, EBV, HSV I and II. The important aspects of preparation are:

NUTRITIONAL REHABILITATION

The preoperative nutritional status has an important bearing on the post-transplant outcome of the child. Modular feeds allowing protein, carbohydrate and fat content to be individually prescribed for each child are recommended. In children with chronic liver disease optimum nutritional status may sometimes be achieved only by nasogastric/nasojejunal feeds including night-time feeds.

IMMUNIZATION

A complete immunization history of the child is a must. Any pending vaccines need to be expatiated prior to transplant ensuring that all the live vaccines have been

Table 2: King's college criteria for non-acetaminophen induced ALF

- PT >100 seconds irrespective of coma grade OR
- Any three of the following, irrespective of coma grade:
- Drug toxicity, indeterminate cause of ALF
 - Age <10 years or >40 years†
 - Jaundice to coma interval >7 days
 - PT >50 seconds (INR >3.5)
 - Serum bilirubin >17.5 mg/dl

Table 3: King's college criteria for acetaminophen induced ALF

- Arterial pH <7.3 (following adequate volume resuscitation) irrespective of coma grade OR
- PT >100 seconds (INR >6.5) + serum creatinine >3.4 mg/dl in patients in grade III/IV coma

administered at least six weeks prior to the transplant in all children with chronic liver disease. However in children undergoing emergency liver transplantation, completing the immunization with live vaccines is not possible.

TREATMENT OF HEPATIC COMPLICATIONS

Ascites and fluid retention is managed by restricted sodium and fluid intake and the use of diuretic therapy. Bleeding varices are treated with intravenous somatostatin or octreotide, endoscopic band ligation or transjugular intrahepatic portal shunts. It is preferable to employ band ligation instead of sclerotherapy because of the potential risk of portal vein thrombosis and ulceration. Hepatic encephalopathy is treated by low-protein diet and oral lactulose. The role of branched chain amino acids remains controversial and use of extracorporeal liver assist devices as a bridge to transplantation is not yet fully established in children.

COUNSELING

Education and counseling of the family and the child is of paramount importance to sustain them through the stressful procedure, the prolonged postoperative period and the life-long immunosuppressive therapy with its attendant risks and side effects.

DONOR SELECTION

Most of the transplantation in developing countries like India constitutes. Living related transplants (LDLT) due the poor availability of cadaver organs. While a lot has been done to increase awareness on organ donation, LDLT continues to be the way forward. In living-donor transplantation, the evaluation and selection of a donor, usually a parent or first-degree relative is performed on the assumption that donor safety can be assured and that the donor's liver function is normal. Donors should be 18 to 55 years of age, and have an ABO-compatible blood type. Following a satisfactory medical and psychological examination by physicians who are not directly involved with the transplantation program, vascular imaging is performed to assess the hepatic arterial anatomy. Donor safety has been excellent in all living donor series.

PROCEDURE

The first description of the procedure in which segments 2 and 3 were procured from a living donor (the mother), and transplanted in a child affected by biliary atresia, dates back to 1988.^{8,9} Living-related liver transplants soon came to account for a substantial number of pediatric cases performed in many centers throughout the world, and the only possibility for liver transplants in countries where cadaveric organ procurement was not allowed until just a few years ago.¹⁰

Living-related liver transplantation has been widely debated with regard to the ethics of performing major surgery on a healthy person. The validity of this procedure is broadly recognized, and over 1200 cases have been performed worldwide, with a donor mortality and morbidity of approximately 0.2 and 10 percent, respectively. Morbidity relates mainly to biliary fistulas, incisional hernias, and bleeding. In the majority of cases, living-related transplants register an excellent outcome for pediatric recipients, thanks to the possibility of performing the transplant before the child's clinical condition deteriorates. Centers with most experience in this area report survival rates between 80 and 90 percent after 1 year.¹¹⁻¹⁶

Postoperative Care

The care of a child after liver transplantation involves a dedicated transplant team. Main issues revolve around graft function in the postoperative period [PT (INR), PTT and other liver function tests] in addition to maintenance of hemodynamic parameters, intake output, abdominal drain output, biliary output and oxygenation to ensure adequate blood flow to liver graft. Strict aseptic precautions must be followed in caring for transplant patients.

Primary nonfunction must be closely monitored for in the first 24 hours (rising transaminases, profound hypoglycemia and acidosis, coagulopathy, oliguria) requiring emergency retransplantation. Hyperacute rejection is rare but can occur (humoral rejection). Five to twenty percent patients will have vascular occlusion with associated graft loss. Vena cava, portal vein and more commonly hepatic artery may get occluded by intramural thrombus, or less commonly by extrinsic compression or vessel kinking. Vessels smaller than 3 mm diameter tend to have higher incidence of arterial thrombosis. Signs and symptoms consist of hepatic failure, increased transaminases and bilirubin levels with worsening coagulopathy. Portal thrombosis presents with fulminant necrosis, intestinal edema with ascites. Doppler ultrasonography and angiography are useful tools. Bile leak and postoperative bleeding must be closely monitored. Early nutrition is important.

About 20 to 50 percent of patients develop at least one episode of acute rejection in the first weeks after liver transplantation. The clinical picture of rejection includes fever, irritability, malaise, leukocytosis, often with eosinophilia, and increased γ -GT, bilirubin, and transaminases. A liver biopsy is required to confirm rejection. The histological triad of endothelialitis, portal triad lymphocyte infiltration with bile duct injury, and hepatic parenchymal cell damage characterizes acute rejection.¹⁷

The primary treatment of rejection is a short course of high-dose steroids. Bolus doses administered over a 3 to 6 day period with a rapid taper to baseline therapy are successful in the majority of cases. When refractory or recurrent rejection occurs, conversions from cyclosporine

to tacrolimus, or antilymphocyte therapy using the monoclonal antibody, ornithine-ketoacid transaminase orthoclone, have been successfully used.^{18,19}

The usual immunosuppressive regimen consists of Calcineurin inhibitors—Cyclosporine or Tacrolimus and prednisolone along with Mycophenolate mofetil (MMF). Tacrolimus based immunosuppression is preferred as it has been associated with less acute rejection and better long-term graft survival rates.

Duration of mechanical ventilation in transplant recipient depends upon age and preoperative condition of the patient. A child with fulminant hepatic failure may require a longer duration of ventilation depending on the neurological state. On the other hand, patients with normal pulmonary function preoperatively may require short-term or no ventilation. Infants and small children are more likely to need postoperative ventilation.

Ventilatory management aims at avoiding the respiratory complications of atelectasis, effusions and pneumonia. Some smaller patients may require a higher end expiratory pressure to compensate for a distended abdomen pushing onto the diaphragm. In a single center series the mean time to extubation was 11.1 ± 15 hours and the mean duration of ICU stay was 7.2 ± 5.5 days.²⁰ Pain control is commonly achieved by opioid infusions titrated to effect. Judicious use of muscle relaxants might be needed. Atracurium (a nondepolarizing muscle relaxant metabolized by nonenzymatic hydrolysis (Hoffman elimination) can be safely used. General principles of respiratory care apply in all mechanically ventilated patients.

Close monitoring, early detection and treatment of complications remains the key to success in addition to supportive management by the liver transplant team.

Immunosuppressive drugs used to prevent rejection inhibit activation of T lymphocytes, medullar cell proliferation and macrophage function, therefore creating an optimal environment for the development of infections. Infectious complications represent a common source of morbidity and mortality after transplantation. Bacterial infections occur in the immediate post-transplantation period and are most often caused by Gram-negative enteric organisms, enterococci, or staphylococci. Replacing or removing all of the intraoperative lines soon after transplantation can minimize sepsis originating at sites of invasive monitoring lines. The use of prophylactic antibacterial antibiotics is discontinued as soon as possible to avoid the development of resistant organisms.

Early and severe viral infections are caused by viruses of the herpes family, including Epstein-Barr virus (EBV), cytomegalovirus (CMV), and herpes simplex virus.²¹ The risk of developing either CMV or EBV infection is influenced by the preoperative serological status of the transplant donor and recipient.^{22,23} Seronegative recipients receiving seropositive donor organs are at greatest risk. Various prophylactic protocols, including intravenous IgG

and hyperimmune anti-CMV IgG, associated with acyclovir or ganciclovir have been used to decrease the incidence of symptomatic CMV and EBV infection, although seroconversion in naive recipients inevitably occurs.^{22,24} The suspicion of CMV infection is suggested by the presence of fever, leukopenia, maculopapular rash and hepatocellular abnormalities, respiratory insufficiency, or gastrointestinal hemorrhage. Hepatic biopsy or endoscopic biopsy of colonic or gastroduodenal sites allows early diagnosis with immunohistochemical recognition. Nowadays, the availability of specific antiviral drugs like ganciclovir, foscarnet and more recently valaciclovir, have radically modified the prognosis of CMV infection.

Herpes simplex virus infections, similar to those seen in nontransplant patients, require treatment with acyclovir when diagnosed. EBV infection represents a potential risk for the pediatric transplant recipient. EBV infection has a variable clinical picture including a mononucleosis-like syndrome, hepatitis-simulating rejection, extranodal lymphoproliferative infiltration, peritonitis or lymph node enlargement, or encephalopathy. Monitoring of EBV blood viral load by quantitative polymerase chain reaction (PCR) is the best predictor of risk. When evidence of active infection exists, an acute reduction in immunosuppression is mandatory. Other post-transplantation infectious complications include adenovirus hepatitis, varicella, and enterovirus induced gastroenteritis. *Pneumocystis carinii* infection has been nearly eliminated by the prophylactic administration of sulfisoxazole and trimethoprim or aerosolized pentamidine.

Outcome Following LT

The overall results following LT are rewarding. The European Liver Transplantation Registry (ELTR) reports liver transplantation activity in Europe, and represents 5895 children transplanted between 1988 and 2005. Overall 1 year patient and graft survival was 84 and 73 percent, respectively, in patients older than 2 years at the time of transplantation, and 81 and 71 percent, respectively, in children <2 years of age. Ten-year patient and graft survival rates for the same age groups were 75 and 61 percent, and 74 and 60 percent, respectively. Similarly, united network for organ sharing in America (UNOS) reported survival rates of the 9064 pediatric patients transplanted between 1997 and 2004. Overall 1 year patient and allograft survival reported to the studies of pediatric liver transplantation (SPLIT) registry, representing 1611 patients, reached 88 and 82 percent, respectively, while these were 83 and 74 percent, respectively, 4 years after transplantation. Specific factors influencing early survival include age, diagnosis, severity of illness, and possibly allograft type.²⁵

In India the first successful pediatric LT was performed in the year 1998. Subsequently more than 150 liver transplants have been performed at various centers

across the country. At present the success rates reported are comparable to the best centers in the west.^{26,27} The surgical expertise gained over the last few years combined with the advancements made and lessons learnt in the medical management have contributed in a big way to this achievement.

However, there is a paucity of reliable cadaver organ supply, primarily due to low awareness about organ donation. This has necessitated the development of living related liver transplantation in a big way. With an appropriate brain death law already in place, sufficient public and professional education is needed to develop cadaver donation. However, with excellent results of LDLT's, this problem is somewhat offset till the time there is more awareness and acceptability towards organ donation in India. The faith and support of the medical fraternity and the public at large has helped in making LT a practically feasible and economically viable treatment modality.

INTRODUCTION

Acute liver failure (ALF) in children is a devastating multi-organ syndrome characterized by sudden and severe liver cell dysfunction in a previously healthy child. This catastrophic illness can rapidly progress to coma and death due to cerebral edema and multiorgan system failure. Excellent intensive care is critical in management of patients with ALF. All pediatric health care providers must be aware of this entity, because early identification and immediate initiation of appropriate supportive therapy will maximize potential for recovery.

There have been recent elaborate reviews and publications on the causal factors, diagnosis, and management of this complex and life-threatening syndrome. In this chapter, we summarize these changes and explain the present best approach to its management.

DEFINITION AND CLASSIFICATION

Since the initial definition of FHF by Trey and Davidson 30 years ago,¹ several classifications have been proposed (Table 1). However, none of these systems have been accepted universally, and overlap in terms and time intervals among them is a source of obvious confusion.

The pediatric acute liver failure (PALF) study group was formed in 2000 as a multisite, multinational consortium to prospectively study ALF in children from birth up to 18 years of age.^{2,3} A consensus reached by 21 PALF investigators defined liver failure as:

- No evidence of a known chronic liver disease
- Hepatic-based coagulopathy that is not corrected within 8 hours by parenteral administration of vitamin K
- Hepatic encephalopathy must be present if the uncorrected prothrombin time (PT) or international

Table 1: Definitions and classifications of acute liver failure

<i>Trey and Davidson</i> ¹	<i>Fulminant hepatic failure: development of HE within 8 weeks of onset of symptoms</i>
<i>O'Grady et al London</i> ⁴ (includes only patients with encephalopathy)	<i>Subclassification depending on the interval between jaundice and HE</i> <i>Hyperacute liver failure: 0 to 7 days</i> <i>Acute liver failure: 8 to 28 days</i> <i>Subacute liver failure: 29 to 72 days</i> <i>Late-onset acute liver failure: 56 to 182 days</i>
<i>Bernuau et al Paris</i> ⁵	<i>Severe acute hepatic failure: Prothrombin time or factor V concentration below 50% of normal with or without HE</i> <i>Subclassification</i> <i>Fulminant hepatic failure: HE within 2 weeks of onset of jaundice</i> <i>Subfulminant hepatic failure: HE between 3 and 12 weeks of onset of jaundice</i>
<i>International Association for the study of the liver</i> ⁶ (occurrence of HE within 4 weeks after onset of symptoms)	<i>Subclassification</i> <i>Acute liver failure—hyperacute: within 10 days</i> <i>Acute liver failure—fulminant: 10 to 30 days</i> <i>Acute liver failure—not otherwise specified</i> <i>Subacute liver failure—development of ascites and/or HE from 5 to 24 weeks after onset of symptoms</i>

FHF—fulminant hepatic failure; HE—hepatic encephalopathy.

normalized ratio (INR) was between 15 and 19.9 seconds or 1.5 to 1.9, respectively

- Hepatic encephalopathy was not required if the PT or INR was greater than or equal to 20 seconds or 2.0, respectively.

This definition is different from adults, as encephalopathy is not necessary because in infants early stages of encephalopathy are difficult to assess, and encephalopathy may not be apparent until terminal stages of ALF.

Also there has been confusion regarding the term used to denote this disease entity like fulminant hepatic failure and fulminant hepatitis or necrosis. It has now been recommended that acute liver failure is a better overall term which includes all durations up to 26 weeks.³

ETIOLOGY AND EPIDEMIOLOGY

ALF can be classified into seven categories: metabolic, infective, toxic, autoimmune, malignancy-induced, vascular-induced, and undetermined. In infants, metabolic disease is the most frequent cause of FHF, whereas in

children, viral FHF is most frequently seen. Whatever the age, undetermined FHF is frequently observed (Table 2).

In the largest study on acute liver failure in children, the pediatric ALF database till December 2006 has enrolled 548 cases, 38 percent of which occurred in children less than 3 years of age. Etiologies were: acetaminophen overdose in 12 percent of cases, metabolic causes in 10 percent of cases, viral hepatitis in 6 percent of cases, ischemia in 4 percent of cases, nonacetaminophen drug-induced liver injury in 4 percent of cases, and other causes in 15 percent of cases; 49 percent were considered indeterminate. While in Indian studies infectious hepatitis is the most important cause of ALF in majority of the cases⁷⁻¹¹ (Table 3).

PATHOGENESIS

The specific pathogenesis of the liver injury is dependent to a large degree on the etiology. But hepatocellular injury is central to FHF, irrespective of the causative agent. The initial insult and interplay of cytokines lead to hepatocyte necrosis or apoptosis.¹²

Table 2: Diagnostic priorities of etiology of FHF by age

	<i>Infectious disease</i>	<i>Cardiovascular</i>	<i>Drugs/toxins</i>	<i>Metabolic/immune</i>
Infant	Herpes simplex Parvovirus Enterovirus EBV Hepatitis B Measles HHV-6	Asphyxia Myocarditis	Paracetamol overdose	Fatty acid defects Mitochondrial defects Galactosemia tyrosinemia Neonatal hemochromatosis Fructose intolerance Niemann-Pick type C
Child	Hepatitis A,B,C,D,E Leptospirosis EBV	Cardiomyopathy Budd-Chiari syndrome Myocarditis	INH Valproic acid Halothane Acetaminophen Vitamin A toxicity	Autoimmune disease Wilson's disease Leukemia Fatty acid oxidation defects Hemophagocytic syndrome Mitochondrial defects NK cell dysfunction
Adolescent	Hepatitis A,B,C,D,E Dengue fever	Congestive heart failure Heat stroke Shock	Acetaminophen MAO inhibitor Tetracycline Mushroom poisoning	Wilson's disease Autoimmune disease Fatty liver of pregnancy Protoporphyrria

EBV—Epstein-Barr virus; INH—isoniazid; Hep—hepatitis; MAO—monoamine oxydase.

Table 3: Indian studies on children with acute liver failure

<i>Year of study</i>	<i>Place of study</i>	<i>n</i>	<i>Etiology being infectious hepatitis</i>
1996	AIIMS, New Delhi	n = 40	75%
1999	Pune	n = 36	61%
2002	Chandigarh	n = 67	94%
2004	SGRH, New Delhi	n = 32	62%
2007	Kolkata	n = 45	66%

An important feature of acute liver injury is the general loss of Kupffer cell function that results in reduced clearance of endotoxin and other substrates regularly presented to hepatocytes by means of the portal system, thus increasing the risk of infection and inflammation.¹³

The site of injury in the liver plays an important role in determining the ability of the liver to regenerate. Arterial blood and portal blood rich in oxygen and nutrients are supplied in the portal tract where the liver progenitor cells, ductal hepatocytes, or oval cells are present. Injury to the portal zone inhibits the regenerative response, while injury to the central zone with sparing of the portal zone permits more frequent spontaneous recovery.¹⁴

With severe hepatocellular injury, liver metabolic functions are impaired. Patients have compromised glucose homeostasis, increased lactate production, impaired synthesis of coagulation factors, and reduced capacity to eliminate drugs, toxins, and bilirubin. As a result, patients develop coagulopathy, hypoglycemia, and acidosis, all of which increase the risk of gastrointestinal bleeding, seizures, and myocardial dysfunction. With ALF, actin scavenger function is compromised by depleted gelsolin.¹⁵ Consequently, actin polymerization occurs, and microvascular function is compromised. The clinical effects of this microvascular injury are manifested by cardiovascular compromise, oxygen exchange abnormalities leading to acute respiratory distress syndrome, renal dysfunction, and disseminated intravascular coagulation (Fig. 1).

CLINICAL FEATURE

The chaos surrounding the patient with ALF makes the initial assessment challenging, but a detailed history and physical examination cannot be overlooked or abbreviated. If a specific diagnosis can be secured, an effective treatment could alter the natural history of the disease.

In viral-induced FHF, jaundice is preceded by symptoms such as fever, myalgia, arthralgia, and nausea. Thereafter, jaundice worsens, liver enzymes become increasingly elevated, and prothombin time becomes prolonged before

hepatic encephalopathy appears, underscoring hepatic dysfunction secondary to significant viral destruction of the liver.

Hepatic encephalopathy (HE) is a neuropsychiatric syndrome associated with hepatic dysfunction and is classified into four grades using a modification of the West Haven criteria^{16,17} (Tables 4 and 5). The patient should be clinically assessed initially and then multiple times during the day for each component of the HE score, as clinical progression can be devastatingly rapid.

Hepatic encephalopathy pathophysiology is complex and multifactorial. Various theories deserve mention:^{18,19}

- The hyperammonemia theory, in which hyperammonemia is thought to have a direct effect on neuronal membranes,
- The false-neurotransmitter theory, in which liver failure causes an increase in aromatic amino acids, decrease in branched-chain amino acids, which results in alterations to brain metabolism.
- The GABA-benzodiazepine theory, which is characterized by increased levels of neuroinhibitory GABA and a synergistic neuroinhibitory effect with benzodiazepine receptor ligands, explaining why, in some cases, use of flumazenil has been shown to reverse encephalopathy without affecting outcome.
- Other theories—abnormal histamine and serotonin neurotransmission, endogenous opioids, neurosteroids, inflammatory cytokines, and potential manganese toxicity.

Ammonia, infection/inflammation, and hyponatremia are the main contributors to the development of brain edema in acute liver failure. Higher arterial ammonia levels were found to be predictive of higher mortality and are associated with more complications including cerebral edema, seizures, and ventilation requirement.²⁰

The World Congress of Gastroenterology has proposed three main categories of HE based on the underlying liver dysfunction.²¹ Type A HE is associated with acute liver failure and progresses rapidly to seizures,

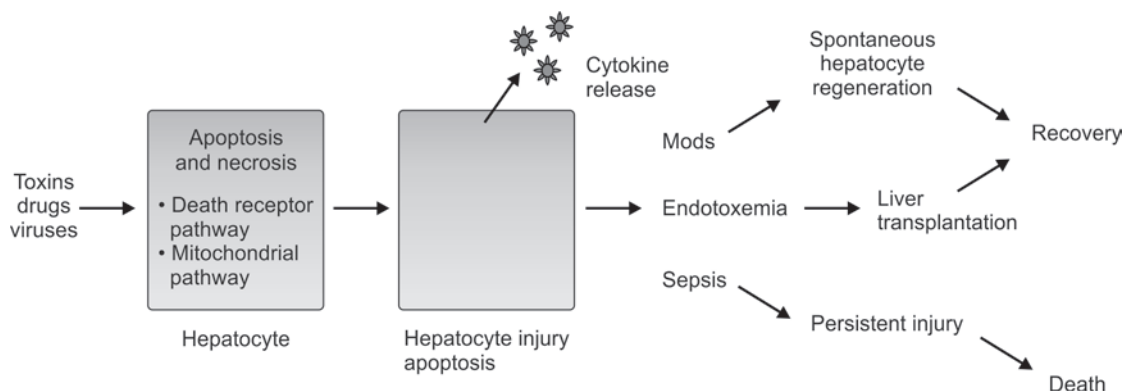

Fig. 1: Pathogenesis of acute liver failure.

Table 4: Stages of hepatic encephalopathy

	<i>Stages</i>			
	<i>I</i>	<i>II</i>	<i>III</i>	<i>IV</i>
Symptoms	Periods of lethargy, euphoria; reversal of day-night sleeping; may be alert	Drowsiness, inappropriate behavior, agitation, wide mood swings, disorientation	Stupor but arousable, confused, incoherent speech	Coma IVa responds to noxious stimuli IVb no response
Signs	Trouble drawing figures, performing mental tasks	Asterixis, fetor hepaticus, incontinence	Asterixis, hyperreflexia, extensor reflexes, rigidity	Areflexia, no asterixis, flaccidity
Electroencephalogram	Normal	Generalized slowing, θ waves	Markedly abnormal, triphasic waves	Markedly abnormal bilateral slowing, δ waves, electric-cortical silence

Adapted from the West Haven criteria.

Table 5: Stages of hepatic encephalopathy for infant and child less than 4 years

	<i>Stages</i>		
	<i>I</i>	<i>II</i>	<i>III</i>
Symptoms	Inconsolable crying, inattention to tasks, child is not acting like self to parents		Stupor, somnolence, combativeness
Signs	Normal or hyper-reflexic. Other neurological signs are difficult to test		Hyper-reflexia, extensor reflexes, rigidity
Electroencephalogram	Difficult to test and interpret		Markedly abnormal, triphasic waves

decerebrate rigidity, coma, and frequently death. Type B is associated with portosystemic bypass with no intrinsic liver disease and type C is associated with cirrhosis and portal hypertension.

DIAGNOSTIC WORK-UP

Initial laboratory tests should be focused in three areas:

- General laboratory investigations to assess hematological, renal, and electrolyte abnormalities (Table 6)
- Diagnostic tests: Prioritize for age and history (Table 7)
- Liver tests: Liver status can be assessed by serial measurement of serum aminotransferase levels, total and direct bilirubin, ammonia, prothrombin time, partial thromboplastin time, lactate and ammonia. A decrease in liver size at a time when the serum bilirubin is rising and serum aminotransferase levels are falling reflects generalized hepatocellular necrosis and parenchymal collapse. To determine if there is evidence of significant liver synthetic dysfunction, factors V, VII, VIII, and fibrinogen should be measured, recognizing that factor VIII levels will be normal even in the face of ALF and also it can differentiate it from DIC, where there will be low factor VIII level.

Table 6: General laboratory investigation

<i>Systems</i>	<i>Laboratory investigations</i>
Hematological	Complete blood cell count with platelets PT—International normalized ratio, aPTT fibrinogen, D—dimer
Electrolytes	Blood glucose, lactate, arterial ammonia, serum osmolarity. Blood gas with pH, Na, K, Ca, Mg, Cl, HCO ₃ , BUN, Cr
Sepsis	CRP, urinalysis and microscopic analysis, blood cultures, urine cultures
Imaging and other testing	Chest radiograph, ECG Abdominal ultrasound with Doppler study of the liver
CNS	EEG, ICP monitor?

MANAGEMENT (FLOW CHART 1)

Advances in critical care medicine and in management strategies have reduced mortality for ALF to approximately

Flow chart 1: Stepwise treatment protocol in FHF

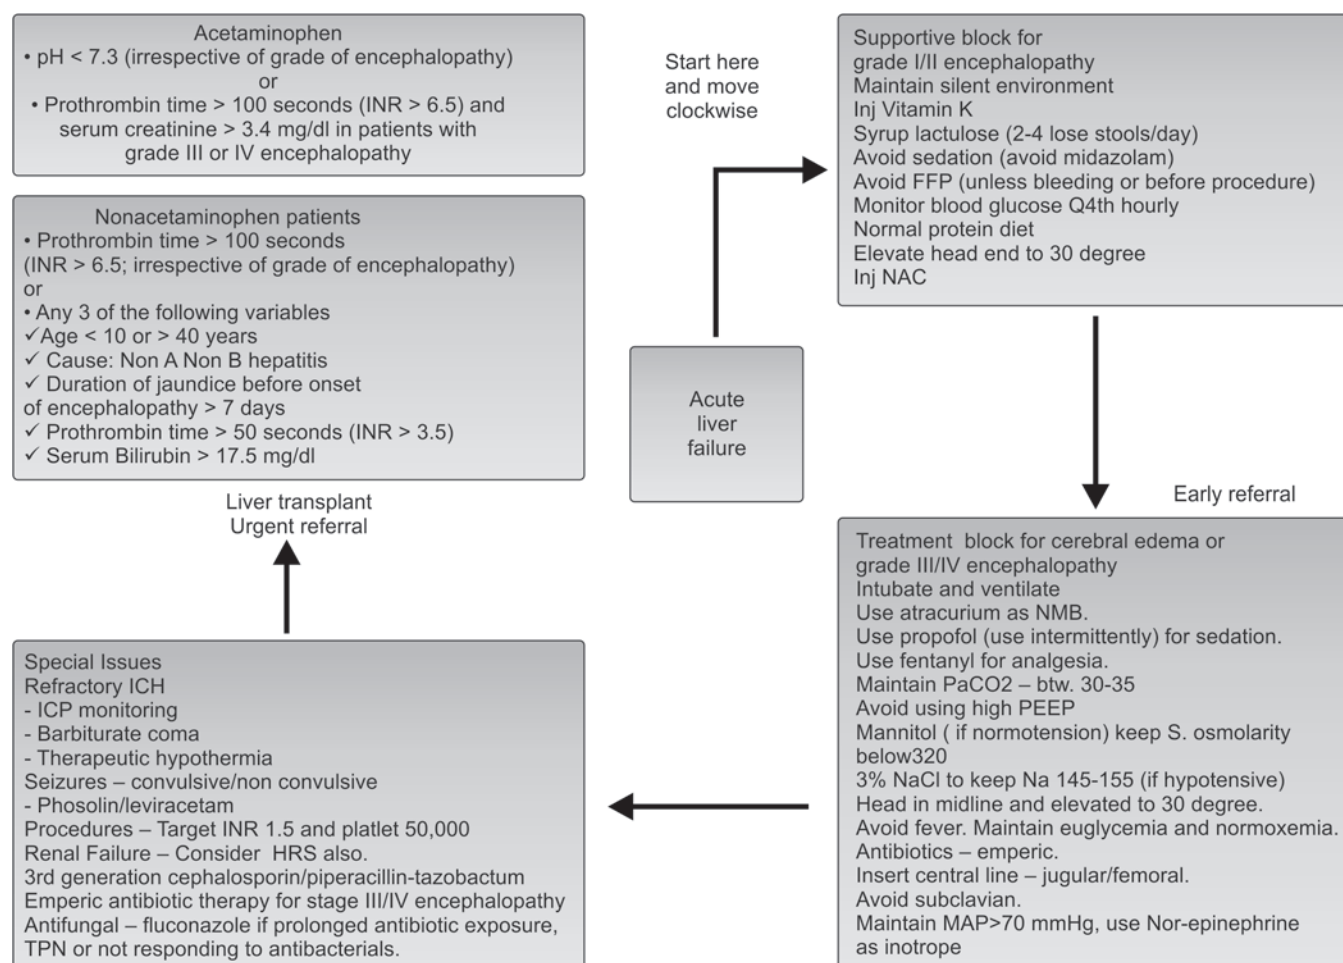

Table 7: Specific diagnostic tests to evaluate etiology of acute liver failure

Cause	Test
Hepatitis A infection	Anti-HAV antibody (IgM)
Hepatitis B infection	Acute infection/ Increased replication Anticore antibody (IgM)/ full hepatitis B virus profile
Hepatitis D infection	Antihepatitis D virus antibody (IgM)
Hepatitis C infection	Antihepatitis C virus antibody (IgM)
Other Infections	HHV-1, 2, 6; CMV; EBV; VZV; echovirus; parvovirus B19
Mushroom poisoning	History, diarrhea
Autoimmune hepatitis	Autoantibodies, immunoglobulins
Wilson's disease	Urinary copper, Kayser-Fleischer rings, Coombs negative hemolytic anemia
Galactosemia	Galactose-1-phosphate uridyl transferase level in the blood
Tyrosinemia	Urinary succinylacetone, wrist radiograph
Neonatal hemochromatosis	Buccal mucosal biopsy, raised ferritin, high transferrin saturation
Hemophagocytic lymphohistiocytosis	Bone marrow aspiration (typical cells)
Mitochondrial hepatopathies	Muscle and liver biopsies for quantitative assay of respiratory chain enzymes
Veno-occlusive disease	Doppler ultrasonography/venography imaging (computed tomography/ magnetic resonance imaging) and histology
Malignancies	Orotic acid
OTC deficiency	Acetaminophen, opiates, barbiturates, cocaine, alcohol
Toxicology screen and drug panel	

33 percent according to the USALF Study Group Registry. This mortality is mainly attributed to three complications in particular: cerebral edema, multiorgan dysfunction syndrome (MODS), and sepsis. The following section will review ICU based management strategies and interventions that have evolved to address the various organ dysfunctions associated with ALF.

PRINCIPLES OF MANAGEMENT

- Monitor and support the patient and organ systems
- Identify and treat complications
- Treat the patient to maximize chances of spontaneous recovery and maintain optimal clinical condition for best post-transplant survival

Although these principles are straightforward, their practical application is more complex and outcomes seem best for patients treated in centers experienced in management of acute liver failure.

Electrolytes and Fluid Therapy

- Hypoglycemia: Hypoglycemia may be present in most of patients with ALF. So regular blood sugar monitoring is mandatory and frequently by finger stick (e.g. every 1-2 hr). Hypoglycemia can worsen hepatic encephalopathy and cause rapid neurological deterioration. Intravenous glucose infusion (6-8 mg/kg/min) is recommended in patients who develop hypoglycemia.
- Dextrose concentration greater than 15 percent—use central line
- Frequent monitoring and correction of other metabolic derangements like hypokalemia, hypophosphatemia, and hypomagnesemia are critical.
- Restrict fluids to 2/3rds maintenance, provided child is hemodynamically stable and avoid fluid overload.
- Use 3 percent NaCl (0.1-1 ml/kg/hour) to maintain Na level between 140 and 150 mEq/L and serum osmolality less than 360 mOsm/L.²²

Ventilation and Monitoring

- Oral intubation is preferred, with a cuffed ETT, due to risk of bleeding and aspiration. Indications of intubation are:
 - > Grade 2 encephalopathy
 - Raised intracranial pressure
 - Rapidly deteriorating course
 - Respiratory failure
 - Cardiovascular collapse
- Aim to oxygenate ($\text{SpO}_2 > 90\%$) and maintain normocarbica (PaCO_2 35-45 mm Hg)
- Avoid high PEEP.
- Excessive hyperventilation should be avoided and not used prophylactic measure but as a transient maneuver to control surges of ICP,²³ as it may paradoxically

compromise the CPP (do not take PaCO_2 level below 30 mm Hg)

- Femoral or jugular central access if vasoactive agents or high concentration dextrose infusions are required.
- The risks and benefits of individual vasopressor agents have not been evaluated carefully, but extrapolation of data from TBI suggests that norepinephrine should be preferred, as it is associated with consistent and predictable increases in CPP.²⁴ Overzealous norepinephrine use should be avoided as this may exacerbate cerebral hyperemia because of the loss of CBF autoregulation in ALF
- Paralyze and sedate with fentanyl/propofol/atracurium.²⁵
- Avoid prolonged propofol infusion (restrict use to <24 hours) in children and in shock.
- Monitor pupils.
- Monitor arterial gases, glucose, sodium, PT (INR) and lactate levels closely.
- Continuous EEG monitoring for nonconvulsive seizure episodes.
- Raise head end of bed to 30 degree (provided patient is not in shock) and keep head in midline.

Cerebral Edema and Intracranial Hypertension

The first line of treatment is to minimize aggravating conditions. Therefore, any precipitating events that can result in hyperammonemia should be avoided. Treatment should include:

- Lowering endogenous nitrogen intake (by limiting bleeding and infection and preventing slowed intestinal transit) or exogenous nitrogen intake (by keeping protein delivery below 0.5 g/kg/day and avoiding unjustified fresh frozen plasma administration)
- Administration of oral or rectal lactulose (4-8 ml/kg, titrated to result in 2 to 4 daily soft stools), is advisable though lactulose use is associated with a small increase in survival but no difference in severity of HE or overall outcome.²⁶
- Neomycin is not recommended and should not be used, as it may precipitate renal failure and has not shown a benefit when combined with lactulose.
- Ornithine aspartate and sodium benzoate have been proposed to decrease serum ammonia, as in Reye syndrome and in urea cycle defects, but hemofiltration remains the main treatment of acute hyperammonemia.
- It is important to consider that minimizing neurosensory and painful stimulation (quiet and darkened room, limited nasopharyngeal aspiration) may help in controlling intracranial pressure (ICP) outburst.
- No consensus exists on the use of invasive ICP monitoring. The ultimate goal of this technique is to maintain adequate cerebral perfusion pressure. However,

an effect on mortality has never been shown.²⁷ Even after a decision is made to proceed with invasive ICP monitoring, the ideal location of placement remains unclear. When invasive monitoring is available the mean arterial pressure (MAP) should be adequate to maintain cerebral perfusion pressure (CPP) between 50 and 80 mm Hg.

- Mannitol can be used as first-line therapy and given as repeated boluses, provided serial serum osmolality remains below 320 mOsm/L, as the equilibrium in osmolality will render the drug ineffective. Its use is limited once patients develop significant renal injury.
- In contrast to mannitol, hypertonic saline can be used as a prophylactic measure with few adverse effects, with a goal of achieving sodium of 145 to 155 mEq/L, provided serum osmolality remains below 360 mOsm/L.¹⁵
 - If osmotic therapies fail to adequately control ICP, other adjunctive measures to reduce ICP include:
 - a. Barbiturate coma (to reduce brain metabolism, although incremental benefit is unclear if the patient is already in stage 4 encephalopathy with coma)
 - b. Paralytic agents
 - c. Phenytoin (may reduce cerebral edema regardless of seizure activity)
- Corticosteroids have been shown to be ineffective in patients with ALF with respect to controlling edema or improving survival
- Moderate hypothermia (32 to 33°C) so far appears to be a formidable tool for managing refractory ICP elevations.²⁸
- Indomethacin (infused intravenously over 1 min) also has been shown to acutely decrease ICP and increase CPP by causing cerebral vasoconstriction. However the use of nonsteroidal drugs in patients with ALF with coagulopathy and renal dysfunction excludes it from routine use without further validation.

Infectious Disease Consideration

Empirical administration of antibiotics is recommended in the following circumstances where infection or the likelihood of impending sepsis is high:²⁹

- Surveillance cultures reveal significant isolates,
- Progression of, or advanced stage (III/IV), hepatic encephalopathy,
- Refractory hypotension;
- Presence of systemic inflammatory response syndrome
- Patients listed for OLT.

Antifungal therapy may be particularly warranted in patients who have had prior antibiotic treatment and for those who have renal failure or the lack of a prompt response to institution of antibacterial therapy and for those patients who are listed for OLT.

The choice of an antimicrobial agent must take into account the need to cover a broad-spectrum of Gram-positive and -negative organisms. In general, third-generation cephalosporin drugs are recommended. Aminoglycosides are to be avoided if possible, owing to their potential for nephrotoxicity. Once speciation from any culture is possible, antimicrobial therapy may be narrowed accordingly.

Selective parenteral and enteral antimicrobial regimen (SPEAR) has shown a 30 percent reduction in the overall frequency of infection compared with those who received antimicrobial treatment when clinically indicated.³⁰ The administration of oral nonabsorbable antibacterials {rifacol} for selective decontamination of the gut does not appear to improve survival in patients already receiving prophylactic systemic antibacterials.³¹

For Gastrointestinal Hemorrhage

- Correct coagulopathy and thrombocytopenia.
- Give vitamin K 5 to 10 mg intravenously.³²
- Ensure packed cells given and more available for transfer, as well as other blood products
- Commence octreotide infusion (0.5-1 mcg/kg/min)
- Consider placing Sengstaken tube (if appropriately trained)
- Patients with ALF in the ICU should receive prophylaxis with H2 blocking agents or PPIs (or sucralfate as a second-line agent) for acid-related gastrointestinal bleeding associated with stress.³

Hematologic Failure: Dealing with Coagulopathy

In the absence of bleeding, it is not recommended to correct homeostasis, because doing so will interfere with the evaluation of liver function (factor V activity, PT). An exception would be if an invasive procedure is planned, such as placement of a central venous catheter. In these cases, procedures can be performed under cover of FFP, platelet or administration of activated recombinant factor VII if profound thrombopenia ($<10,000/\text{mm}^3$) is observed. Although strict guidelines do not exist, a rough target would be to correct the INR to approximately 1.5 and platelet count to approximately $50,000/\text{mm}^3$ before procedures with the use of fresh frozen plasma (FFP) and platelets. Concomitant administration of cryoprecipitate is recommended for patients who have significant hypofibrinogenemia (less than 100 mg/dl). When FFP fails to adequately normalize PT/INR, the use of recombinant factor 7a (rF7) can be considered. FFP or cryoprecipitate should be administered before rF7 (40 $\mu\text{g/kg}$) if fibrinogen levels are less than 100 mg/dl to replete factors involved in the clotting cascade.³³

Acute Kidney Injury

Acute kidney injury is multifactorial in the setting of ALF. Acute renal failure denotes a poor prognosis and

contributes to mortality. Hypovolemia, low systemic vascular resistance, acute tubular necrosis (ATN), GI blood loss and hepatorenal syndrome are among the most important associated entities. Renal toxic agents should be avoided.

Hepatorenal syndrome, defined as a progressive renal insufficiency in patients with liver disease, is characterized by a low urine sodium output and elevated urinary-to-plasma ratios for creatinine and osmolality. In patients with FHF, type 1 hepatorenal syndrome is found and defined as a rapid and progressive renal impairment. The pathogenesis is poorly understood; however, it is characterized by renal cortical vasoconstriction and corticomedullary redistribution of renal blood flow. Hepatorenal syndrome may be precipitated after digestive bleeding, septicemia, and dehydration.

Where available continuous venovenous hemofiltration (CVVHF) is preferred method of renal replacement because of the reduced shifts in blood pressure associated with its use. Anticoagulation of renal replacement circuits can be problematic and the most units avoid systemic heparinization. Due to this knowledge most liver transplant centers use citrate for patient with ALF or postliver transplant.³⁴

NUTRITION

There is a need for nutritional supplementation in ALF, because these patients are catabolic and enteral nutrition should be administered whenever possible, with higher caloric density feeds preferred to avoid excessive free water and hypo-osmolality, which may exacerbate cerebral edema. Parenteral nutrition (35-40 kcal/kg per day) delivered by a dedicated central venous catheter, should be reserved for patients with specific contraindications to enteral nutrition. Normal protein intake recommended till Stage I and II encephalopathy and thereafter restriction is recommended. Excess glutamine supplementation

should be avoided given glutamine's role in the production of ammonia and development of cerebral edema in ALF.³⁵

ETIOLOGY SPECIFIC TREATMENT

Table 8 describes etiology specific treatment.

Liver Support Systems

A support device to replace the acutely failing liver seems a reasonable but elusive goal. The ideal replacement for the failing liver would detoxify, metabolize and synthesize; in short, perform all the liver's many functions. A variety of systems have been tested to date, with no certain evidence of efficacy. Currently available liver support systems are not recommended outside of clinical trials; their future in the management of acute liver failure remains unclear.³⁶

N-acetylcysteine

When used early as an antidote after a single, intentional paracetamol overdose, NAC is extremely effective at replenishing hepatic glutathione stores and preventing severe N-acetyl-p-benzoquinone imine induced hepatotoxicity and liver failure.

N-acetylcysteine is now also used to treat established FHF of any cause, because of its antioxidant effects and improved tissue oxygenation and is efficacious if given early in liver failure.³⁷ The optimal duration of NAC therapy in these patients is unclear; some say till reversal of encephalopathy at a dose of 100 mg/kg/day in 5 percent Dextrose or for 3 days.

Liver Transplantation

Emergency liver transplantation remains the only treatment of end-stage FHF in children. Transplantation decisions rely on the cause and severity of FHF and the

Table 8: Target specific therapy of underlying ALF

<i>Cause</i>	<i>Treatment</i>
Hereditary tyrosinemia	Nitisinone (NTBC) 1 mg/kg/day orally in 2 doses
Neonatal hemochromatosis	Deferoxamine 30 mg/kg/day IV in 3 doses. Selenium 2-3 mcg/kg/day IV N-acetyl-cysteine 140 mg/kg, then 70 mg/kg orally or IV tocopherol polyethylene glycol succinate 20 UI/kg/day orally
Herpetic hepatitis	Acyclovir 150 mg/m ² /day IV
Acetaminophen poisoning	Activated charcoal 1 g/kg orally N-acetylcysteine 150 mg/kg IV in 15 min, then maintenance dose 50 mg/kg over 4 hours, followed by 100 mg/kg administered over 16 hours
Mushroom poisoning	Penicillin G 300,000-1 million units/kg/day IV. Silymarin 30-40 mg/kg/day IV or orally
Hepatitis B	Lamivudine 4 mg/kg/day once daily orally
HSV	Acyclovir 10 mg/kg 8 hourly
Autoimmune hepatitis	Methylprednisolone 60 mg/kg IV

Table 9: Indications to discuss emergency liver transplantation with parents

1. Hepatic encephalopathy grade II with	Factor V activity of <20%
	Worsening prothrombin time
2. Other criteria	Rapid decrease in liver size
	Seizures, ascites, hepatorenal syndrome
	Fibrinogen level of <1g/L, bilirubinemia of >23 mg/dl
	Worsening lactic acidosis and hyperammonemia of >150 mmol/L

Table 10: King’s college hospital and clichy liver transplantation criteria for fulminant hepatic failure

	<i>King’s College criteria</i>
FHF secondary to acetaminophen overdose	pH less than 7.30 (irrespective of encephalopathy grade), Or Hepatic encephalopathy grade III–IV, Prothrombin time over 100 seconds (INR > 6.5), and Serum creatinine over 300 μmol/L (3.4 mg/dl)
FHF with other causes	Prothrombin time over 100 seconds (INR > 6.5) (irrespective of encephalopathy grade), Or any three of the following (irrespective of encephalopathy grade) Age under 10 or over 40 years Non-A, non-B hepatitis or drug-induced origin Duration of jaundice before encephalopathy over 7 days Serum bilirubin greater than 300 μmol/l (17.6 mg/dl) Prothrombin time over 50 seconds (INR > 3.5)
	<i>Clichy criteria</i>
Presence of confusion or coma (stage III–IV HE) associated with	
Factor V level lower than 20% of normal in patients aged less than 30 years	
Factor V level lower than 30% of normal in patients aged over 30 years	

potentialities of spontaneous liver regeneration and the comorbidities, especially the development of permanent neurologic damage. In adults, the most commonly used transplantation criteria are those developed at King’s College in London (Tables 9 and 10) and Beaujon’s Hospital in Paris.³⁸ However, these criteria fail to be adequate in children, mainly due to a very weak negative predictive value. In children, etiology is a critical determinant of outcome. Fulminant Wilson disease and undetermined FHF carry the worst prognosis and require emergency liver transplantation, whereas hepatitis A-induced and acetaminophen-induced FHF have significant spontaneous recovery without transplantation. Other FHF causes have variable outcome, mainly determined by the severity of neurologic involvement.

Liver transplantation may be contraindicated in 11 to 20 percent of cases. For instance, malignant disease, such as leukemia, lymphoproliferative syndrome, lymphohistiocytosis, and some mitochondrial respiratory chain disorders, as well as the patient’s end-stage intracranial

hypertension or uncontrolled multiorgan failure, are contraindications to transplantation due to poor outcome.

OUTCOME

FHF prognosis has significantly improved since the performance of the initial series of emergency liver transplantations, shifting from an overall survival of 15 to >60 percent.³⁹ In children, published experience of emergency liver transplantation in the setting of FHF shows long-term survival ranging from 52 percent in infants to 79 percent in older children. Mostly a short interval between symptoms or jaundice and encephalopathy (most of acetaminophen-induced FHF and some of hepatitis A or B etiology) is associated with the high-risk of brain edema and greater possibility of spontaneous recovery, whereas a long interval is associated with less frequency of brain edema, lower survival, and more common non-A-to-E cryptogenic etiology. A study of FHF in the SPLIT (The Studies in Pediatric Liver Transplantation) database suggested that grade 4 encephalopathy, age less than 1

year and dialysis before transplantation were risk factors for poor outcomes.⁴⁰

KEY POINTS

Author's Experience on Liver Transplantation Till October 2011

- Infants and children with FHF should be referred early to centers with expertise in pediatric liver disease, as determination of an accurate etiologic diagnosis before encephalopathy occurs is critical.
- In pediatrics—presence of encephalopathy is not essential for diagnosing acute liver failure.
- Fresh frozen plasma should be avoided as long as no active bleeding is present. It will modify coagulation factors for 24 hours that are important criteria by which to evaluate FHF severity.
- Encephalopathy and coagulation parameter (factor V activity, PT) kinetics are major FHF severity criteria that aid in deciding whether to perform emergency liver transplantation.
- NAC is of beneficial role even in nonacetaminophen acute liver failure, when given early.
- Liver transplantation has drastically changed prognosis of pediatric FHF and end-stage liver disease.

DEFINITION

Acute diarrhea is the abrupt onset of increased fluid content of the stool above the normal. Normally stool output in infants and toddlers is up to 10 ml/kg/d, while in older children and adults it is up to 200 gm per day. Practically this manifests as loose or liquid stools (decrease in stool consistency) and an increase in stool frequency to ≥ 3 bowel movements per day. The increased frequency of bowel movements can range from 4 to more than 20 times per day. The increased fluid content of the stools is the result of an imbalance in the absorption and secretion of electrolytes, organic substrates, and hence water by the small and large intestine.

In terms of duration acute diarrhea is classically defined as an episode of diarrhea that has an acute onset and lasts no longer than 14 days; while as an episode lasting more than 14 days is called as persistent diarrhea.

EPIDEMIOLOGY

Acute diarrhea most often results from infections of the gastrointestinal tract. It is a major problem for child health worldwide. Diarrheal diseases are one of the leading causes of morbidity and mortality in children worldwide. There are about one billion episodes of illness annually. Although in developed countries the prevalence and severity of acute diarrhea has declined, it remains a common and often a severe problem. In developing countries, children suffer from an average of 3 (up to 6-8 in some areas) episodes of diarrhea per year during first 5 years of life. Childhood mortality associated with diarrhea has constantly but slowly declined during the past two decades, mostly because of the widespread use of oral rehydration solutions (ORSs), but still remains high with 3 to 5 million deaths annually.

Person to person transmission through the fecal-oral route or by ingestion of contaminated food or water is the

major mechanisms of transmission for diarrheal pathogens. Factors that increase susceptibility to infection with enteropathogens include young age, immune deficiency, measles, malnutrition, lack of breast-feeding, exposure to unsanitary conditions, ingestion of contaminated food or water, level of maternal education, and attendance at a childcare center.

ETIOLOGY

Gastrointestinal infections are by far the most common cause of acute diarrhea. However the sudden onset of increased stool fluid output can also be caused by many noninfectious disorders. Causative agent can be identified in >70 percent of cases of acute diarrhea in good laboratories.

Infections of the gastrointestinal tract are caused by a wide variety of enteropathogens, including bacteria, viruses, and parasites.

- *Viruses*
 - Rotavirus
 - Calicivirus
 - Norwalk-like virus
 - Astrovirus
 - Enteric-type adenovirus
- *Bacteria*
 - *Campylobacter jejuni*
 - *Salmonella*
 - *Escherichia coli*
 - (i) Enterotoxigenic (ETEC)
 - (ii) Enteropathogenic (EPEC)
 - (iii) Enteroinvasive (EIEC)
 - (iv) Enterohemorrhagic (EHEC)
 - (v) Enterotoxigenic (EAggEC)
 - (vi) Diffusely adherent (DA-EC)
 - *Shigella*
 - *Yersinia enterocolitica*
 - *Clostridium difficile*

- *Vibrio parahaemolyticus*
- *Vibrio cholerae* 01& 0139
- *Vibrio cholerae* non-01
- *Aeromonas hydrophila*
- *Parasites*
 - *Cryptosporidium*
 - *Giardia lamblia*
- *Non-gastrointestinal infections*
 - Otitis media
 - Urinary tract infections
 - Pneumonia
- *Non-infectious causes*
 - Drugs induced, e.g. antibiotics
 - Food allergy (Cow's milk protein, soy protein)
 - Disaccharidase deficiency (sucrase-isomaltase, hypolactasia)
 - Chemotherapy or radiation-induced enteritis
 - Acute appendicitis
 - Intussusceptions
 - Niacin deficiency
 - Ingestion of heavy metals

In India rotavirus and ETEC account for more than half of cases of acute diarrhea.

PATHOGENESIS

The two basic types of acute infectious diarrhea are non-inflammatory and inflammatory. Enteropathogens elicit noninflammatory diarrhea through enterotoxin production by some bacteria, destruction of villus (surface) cells by viruses, adherence by parasites, and adherence and/or translocation by bacteria. Noninflammatory diarrhea may be caused by enteropathogenic *E. coli*, enterotoxigenic *E. coli*, *Vibrio cholerae*. In contrast, inflammatory diarrhea usually is caused by bacteria that invade the intestine directly or produce cytotoxins. Generally, inflammatory diarrhea is associated with *Aeromonas*, *Campylobacter jejuni*, *Clostridium difficile*, enteroinvasive *E. coli*, Shiga toxin-producing *E. coli* (*E. coli* O157:H7), *Plesiomonas shigelloides*, *Salmonella*, *Shigella*, *Vibrio parahaemolyticus*, and *Yersinia enterocolitica*. Some enteropathogens possess more than one virulence property.

CLINICAL FEATURES

Laboratory Investigations

- Often are not required as most episodes of acute diarrhea are self-limited
- Stool may be examination for mucus, blood, and leukocytes, the presence of which indicates colitis
- Stool leukocyte (>50/hpf) indicates the presence of an invasive or cytotoxin-producing organism such as *Shigella*, *Salmonella*, *C. jejuni*, invasive *E. coli*, *C. difficile*, *Y. enterocolitica*.

- Stool culture – to identify organism is not done routinely. *E. coli* is often reported on stool cultures but it can be a commensal. Serotype and toxin assays are available for further characterization of *E. coli*.
- Proctosigmoidoscopy may be helpful in establishing a diagnosis in patients in whom symptoms of colitis are severe or the cause remains obscure.
- Serum electrolytes, BUN, creatinine and arterial blood gas estimation should be done when clinical indicated.

APPROACH TO CHILDREN WITH ACUTE DIARRHEA

The main objectives in the approach to a child with acute diarrhea are to (1) assess the degree of dehydration and provide fluid and electrolyte replacement, (2) prevent spread of the enteropathogen and (3) in select episodes determine the etiologic agent and provide specific therapy if indicated. Information about oral intake, frequency and volume of stool output, general appearance and activity of the child, and frequency of urination must be obtained. The duration and severity of diarrhea, stool consistency, presence of mucus and blood, and other associated symptomatology, such as fever, vomiting, and seizures, should be determined.

Fever suggests a systemic infection, inflammatory diarrhea but also occurs as a result of dehydration. Although nausea and vomiting are nonspecific symptoms, vomiting suggests upper intestinal involvement, as occurs in enteric viruses, enterotoxin-producing bacteria, *Giardia*, and *Cryptosporidium*. Emesis, absent or low-grade fever, mild crampy periumbilical pain and watery diarrhea indicate upper intestinal tract involvement and hence noninflammatory diarrhea. Fever, lower abdominal pain, tenesmus, blood and mucus in stools indicate large intestinal involvement and hence inflammatory diarrhea.

Assessment of Dehydration

During diarrhea there is a net loss of water and electrolytes from the body and the child develops symptoms and signs of dehydration. Based on these symptoms and signs the dehydration status of child is graded into no dehydration, some dehydration and severe dehydration as per WHO criteria given in Table 1.

Treatment Plan A

If a child has diarrhea but no signs of dehydration, treatment plan A is used (Table 2). The aim of this treatment is to prevent dehydration by replacing ongoing fluid and electrolyte loss in stools. Most fluids (preferably one containing salt) that a child normally drinks can be used. These include ORS solution, salted rice water, salted yoghurt water, soup with salt, coconut water and plain water. Carbonated beverages, commercial fruit juices, sweetened tea and coffee should be avoided as they have

Table 1: Assessment of dehydration in children with diarrhea

		<i>A</i>	<i>B</i>	<i>C</i>
Look at	General Condition ^a	Well, alert	Restless, irritable	Lethargic or unconscious
	Eyes ^b	Normal	Sunken	Very sunken, dry
	Tears	Present	Absent	Absent
	Mouth + tongue ^c	Moist	Dry	Very dry
	Thirst	Drinks normally, not thirsty	Thirsty, drinks eagerly	Drinks poorly or not able to drink
Feel	Skin pinch ^d	Goes back quickly	Goes back slowly	Goes back very slowly
Decide	Degree of dehydration	No dehydration	Some dehydration if ≥ 2 signs in B	Severe dehydration if ≥ 2 signs in C
Treat using		Plan A	Plan B after weighing if possible	Plan C after weighing the child

- a. Being lethargic and sleepy are not same. Lethargic child is not simply asleep: child's mental state is dull, cannot be fully awakened and may appear to be drifting into unconsciousness.
- b. It is helpful to ask mother if the eyes are normal or more sunken than usual as they may appear somewhat sunken normally in some infants and children.
- c. Dryness of mouth and tongue can also be palpated using a clean finger. It may occur in habitual mouth breathers. They may be wet owing to recent vomiting or drinking.
- d. Skin pinch is less useful in marasmus, edematous malnutrition and obese children.

Table 2: Guidelines for treating children with no dehydration – Plan A

<i>Age</i>	<i>Amount of ORS/ORT after each stool</i>	<i>ORS to be provided for home use</i>
<24 months	50-100 ml	500 ml/day
2-10 years	100-200 ml	1000 ml/day
≥ 10 years	As much as wants	2000 ml/day

Demonstrate to mother how to prepare and give ORS and amount to be given after each stool using local measures.

Give a teaspoonful every 1-2 minutes to children < 2 years.

Give frequent sips from a cup to older children.

If child vomits, wait for 10 minutes, then give ORS more slowly.

a high osmolality and can worsen dehydration by causing osmotic diarrhea and diuresis. Generally as much fluid as the child wants should be offered until diarrhea stops. The mother should be instructed to bring the child to health care facility if the child does not improve in three days or any of the following danger signs develops: high purge rate, repeated vomiting, marked thirst, eating or drinking poorly, fever or blood in stools.

Treatment Plan B

Children with some dehydration should be treated using plan B (Table 3) in a health care facility. The aim is to correct the existing deficit, to replace ongoing loss and to provide normal daily requirement of fluid and electrolytes. Give 75 ml/kg of ORS over a period of 4 hours. Use age appropriate guidelines for amount of fluid to be

given if weight is not known. Watch for signs of overhydration or worsening of dehydration. If signs of severe dehydration develop, shift to plan C. After 4 hours the hydration status of child should be reassessed. If signs of some dehydration are corrected, child should be offered ORS to replace ongoing stool losses till diarrhea stops (plan A). If child continues to have signs of some dehydration, initiate another 4 hours treatment with ORS solution and start to offer feeds, milk and breast feeding frequently.

Oral Rehydration Therapy (ORT)

The term ORT encompasses:

- Oral rehydration salt (ORS) solution with composition as recommended by WHO
- Solutions made from sugar and salt.

Table 3: Guidelines for treating children with some dehydration – Plan B

Approximate amount of ORS solution to be given in first 4 hours

Age	<4 months	4-11 months	11-23 months	2-4 years	5-14 years	≥15 years
Weight (kg)	<5	5-8	8-11	11-16	16-30	>30
ORS (ml)	200-400	400-600	600-800	800-1200	1200-2200	2200-4000
Local measure	1-2	2-3	3-4	4-6	6-11	12-24

Note: Approximate amount of ORS can be calculated by multiplying child's weight in kg by 75

- Food based solutions.
- A variety of commonly available, culturally acceptable fluids.

ORS is the most commonly used ORT fluid and refers to the oral rehydration salt solution as recommended by WHO. In 2002 WHO recommended the new low/reduced osmolarity ORS in place of standard WHO ORS 1975. In 2004 Government of India based on recommendations of WHO/UNICEF and IAP adopted the reduced/low osmolarity ORS as the single universal ORS to be used for all ages and all types of diarrhea. Table 4 shows the comparison between reduced/low osmolarity WHO ORS and standard WHO ORS. Reduced osmolarity ORS when compared to WHO standard ORS is associated with reduced need for intravenous fluid infusions, lower stool volume, less vomiting and no increased risk of hyponatremia. These advantages led the WHO to recommend reduced-osmolarity ORS as a global ORS in 2002.

Oral rehydration therapy is effective in correcting dehydration in 95 to 97 percent of children. However in 3-5 percent of children ORT failure occurs and such children need parenteral fluids to correct some dehydration. The ORT failure may be due to:

- High purge rate
- Frequent vomiting
- Incorrect preparation, amount or administration
- Abdominal distention with ileus.

- Glucose malabsorption (rare, increased diarrhea after starting ORS)

Treatment Plan C

The preferred treatment for children with severe dehydration is rapid intravenous rehydration as per plan C (Table 5). Start intravenous fluids immediately. However if IV fluids cannot be started immediately (due to no IV access, non availability, or during transport) one can start rehydration with ORS using nasogastric tube till IV access is established. The best IV fluid is Ringer's lactate solution. Normal saline solution can be used if Ringer's lactate solution is not available. Plain dextrose solutions are not effective.

Feeding

ORT itself has a beneficial effect on nutrition by stimulating the child's appetite as a result of the improved water and potassium balance. Furthermore, rapid re-feeding after adequate ORT has been shown to allow a faster recovery from the abnormally increased intestinal permeability.

It has been clear for many years that, breastfed infants should be continued on breast milk without any need for interruption. Breastfeeding not only has a well-known protective effect against the development of enteritis,

Table 4: Comparison between new (reduced osmolarity) and old (standard) WHO ORS

Ingredient	Concentration (mmol/L)	
	Reduced osmolarity WHO ORS (2002)	Standard WHO ORS (1975)
Sodium	75	90
Potassium	20	20
Chloride	65	80
Citrate/bicarbonate	10/30	10/30
Glucose	75	111
Osmolarity	245	311

Table 5: Guidelines for intravenous fluid therapy in severe dehydration

Age	First give	Then give
<12 months	30 ml/kg in 1 hour*	70 ml/kg over next 5 hours
>12 months	30 ml/kg in ½ hour*	70 ml/kg over next 2 ½ hours

*Repeat if radial pulse is still very weak or not detectable.

Use Ringer's lactate solution or normal saline if former is not available.

it also promotes faster recovery and provides improved nutrition.

Lactose intolerance is not a major problem in children with diarrhea and should not be a reason to delay re-feeding milk-based formulas. Very rarely, if fecal pH decreases and more than 0.5 to 1 percent reducing substances are found in the stools, lactose intolerance should be assumed and a lactose-free formula employed at least temporarily to prevent persistent diarrhea.

In children with no dehydration feeding should be continued with usual foods and breast milk (if breast fed). In children with some dehydration breast feeding should be continued during rehydration. In non breastfed children milk preferably mixed with cereals and other semi-solid foods should be offered soon after correction of deficit. Small frequent meals are better tolerated.

During recovery an intake of 1.25 times the normal RDA should be given in the form of energy dense food till child achieves normal weight for age. This may take several weeks.

ANTIBIOTICS

Majority of cases of acute diarrhea in children are caused by viruses and such bacteria, wherein it is neither necessary nor desirable to use antibiotics. In fact enteric bacterial pathogens show increased resistance to standard therapy, antibiotics are variably effective, and their use may prolong the carrier state.

The recommendation for antimicrobial treatment in immunocompetent children with acute diarrhea are:

- Agents for whom antimicrobial therapy is always indicated; these include *V. cholerae*, *Shigella*, and *Giardia lamblia*, *E. histolytica*
- Agents for whom antimicrobial therapy is indicated only in selected circumstance:
 - infections by enteropathogenic *E. coli*, when running a prolonged course.
 - enteroinvasive *E. coli*, based on the serologic, genetic, and pathogenic similarities with *Shigella*.
 - *Yersinia* infections in subjects with sickle cell disease and
 - *Salmonella* infections in the very young infants, if febrile, or with positive blood culture.

Antibiotics to which enteric pathogens remain sensitive and are generally used include fluoroquinolones (e.g. ciprofloxacin, ofloxacin) and third generation cephalosporins (e.g. cefixime, ceftriaxone). *E. histolytica* and *G. lamblia* are usually treated with metronidazole.

Zinc in Treatment of Acute Diarrhea

Zinc deficiency is widely prevalent in children of developing world. In the past few years, a great deal of interest has been generated in the possible role of zinc supplementation in either the prevention or treatment of acute diarrhea in children of developing countries. Several studies are now available which show that zinc supplementation to children with acute diarrhea results in shorter duration of diarrhea, lesser stool output, better weight gain, improved zinc serum status and reduces the incidence of diarrhea for next 3 months. Zinc supplementation is now part of standard management along with ORS for treatment of acute diarrhea. The dose of elemental zinc in acute diarrhea is 20 mg/day (10 mg/day for infants < 6 months of age) for 10 to 14 days.

IMMUNOGLOBULINS

Several studies have shown efficacy of oral/entral immunoglobulin in the treatment and prevention of rotavirus diarrhea. Although this approach may benefit certain infants with severe, protracted rotavirus diarrhea (e.g. immunocompromised) it is not recommended in routine management of rotavirus diarrhea.

ANTI-DIARRHEAL DRUGS

The anti-diarrheal drugs can be categorized into:

- Anti motility, e.g. loperamide, diphenoxylate.
- Binding, e.g. pectin, kaolin, bismuth.
- Anti secretory, e.g. racecadotril, octreotide.

Racecadotril a potent synthetic enkephalinase inhibitor, promotes absorption and having no effect on intestinal motility has shown safety and effectiveness in treatment of acute diarrhea but requires further large clinical trials.

In general it can be said that no anti-diarrheal drugs can and should presently be recommended in children with acute diarrhea.

PROBIOTICS

Probiotics are live microflora meant to have beneficial effect on host. This is one of the hotly researched areas in treatment and prevention of diarrheal diseases. The use of several strains of lactic acid bacteria to treat human diseases is centuries old and lactobacilli are among the most commonly employed bacterial species used to promote health and counteract intestinal infections. Table 6 lists the common probiotics investigated in medical practice.

Among them *Lactobacillus rhamnosus* strain GG is by far the most widely investigated and has shown beneficial effect in treatment and prevention of acute diarrhea especially viral diarrhea. Probiotics in the form of *Saccharomyces boulardii* and *Lactobacillus* GG have also shown efficacy in prevention of antibiotic associated diarrhea.

PREVENTION

Global efforts to reduce the continuing high morbidity and mortality due to diarrheal diseases are being led by WHO and the targeted areas include education, proper

hygiene and sanitation, promotion of breast feeding, food safety and ORT, probiotics and development of vaccines. Simple hand washing with soap decreases the incidence of diarrhea by more than 50 percent, as does education campaigns focused on proper hygiene and sanitation, promotion of breast feeding, food safety and ORT.

Vaccination is now available against rotavirus and has been shown to prevent severe rotavirus diarrhea and associated hospitalizations. Rotarix (Glaxo SmithKline biological) and RotaTeq (Merck and company), both live attenuated vaccines have been licensed for use in humans. Both are safe and have not been shown to be associated with increased risk of intussusceptions.

INTRODUCTION

Diarrheal diseases account globally for almost a fifth of all deaths in children less than 5 years of age with an estimated 2.2 million annual deaths.¹ Most episodes of acute diarrhea settle in less than 7 days; however a small but significant proportion are prolonged or persistent lasting longer than 7 to 14 days. These prolonged or persistent episodes contribute not only to a considerable share of the global burden of diarrheal disease in children less than 5 years of age but are also implicated in undernutrition, micronutrient deficiencies, growth faltering, cognitive impairment and higher morbidity and mortality when associated with other diseases. The reported annual disability adjusted life years lost due to persistent diarrhea is also staggeringly high being around 3 million. Therefore, it is imperative that pediatricians are aware of the epidemiology, etiology, risk factors, pathophysiology and management of persistent diarrhea, a preventable morbid continuum of acute diarrhea which is prevalent in developing countries.

DEFINITIONS

Persistent Diarrhea

WHO defined *persistent diarrhea* (PD) as an illness of presumed infectious etiology with an acute onset lasting for more than 14 days excluding conditions, such as celiac disease or other hereditary disorders.² Since the main disturbing feature of PD is growth faltering or undernutrition which is not included in this definition, it may be preferable to express persistent diarrhea as “with or without weight loss”.

The *14 days cut-off point* between acute diarrhea and persistent diarrhea is arbitrary but in 1989, Bhan et al, in a large prospective study clearly documented the sharp rise

in mortality from 0.7 percent in shorter duration illness to 14 percent in PD supporting the necessity of this “two week cut-off” mark.³ Bhutta et al in 2008 emphasized the issue that since the majority of acute diarrheal episodes resolve within 5 to 7 days, it may be necessary to be alert and more cautious in managing children in the interim period of 7 to 14 days in order to avert the major consequences of PD.⁴ The label *prolonged diarrhea (ProD)* for this exclusive episode of >7 days and <14 days diarrhea utilized by Moore et al was to highlight the point that it may be an indicator for children with a high risk for progression to PD.

There are two other diarrheal diseases which are similar in the duration of illness but are different in pathophysiology and prognosis and therefore should be considered as different entities to have a uniform understanding.

Protracted Diarrhea of Infancy

Protracted diarrhea of infancy (PDI) is defined as diarrhea lasting for more than 2 weeks with failure to thrive and requiring specialized enteral or parenteral nutritional support. Avery Jones described this unique entity as early as 1968 in infants less than 3 months of age; later Guarino in 1995 increased the age limit to children less than 2 years of age.

Chronic Diarrhea

Chronic diarrhea (CD) is defined as a diarrheal illness of insidious onset, usually of noninfectious etiology and lasting for more than 14 days which is associated with malnutrition either due to maldigestion or malabsorption of nutrients. The main difference between PD and CD is the presence of an underlying inherent defect such as celiac disease, intestinal lymphangiectasia, etc. in CD which are not included in the diagnostic criteria for PD.

EPIDEMIOLOGY

The burden of persistent diarrhea varies in different regions and accounts for approximately 3 to 23 percent (average 10%) of all diarrheal illness. In India, five percent of all diarrheal episodes was identified as persistent;³ similar studies from Brazil, Peru and Israel indicated that 5 to 18 percent of diarrheal episodes were persistent. In Brazil, 12 percent of all episodes were prolonged with a 6-fold increase of progression to PD. Diarrheal deaths directly related to PD varies from 36 to 54 percent and is related to the environmental characteristics and utilization of medical facilities. Persistent diarrhea is more common in malnourished children and in those less than two years of age. Sixty percent of PD occurs before 6 months and 90 percent below 1 year of age. Boys seem to be more affected than girls. Twenty percent of acute diarrheal episodes in malnourished children persists beyond two weeks. A community-based study from Bangladesh in 2003 has reported that PD accounts for less than 0.5 percent of diarrheal episodes. There is no definite evidence that the global incidence of PD has declined though it appears to be overall less, probably because the number of publications related to PD has decreased over the last decade. There is a definite need to update data regarding the present prevalence of PD.

ETIOPATHOGENESIS AND PATHOPHYSIOLOGY

The etiopathogenesis of PD is not well understood and is probably multifactorial. There is a definite interplay between persistent mucosal injury due to specific pathogens (*E. coli*, *Shigella*, *Salmonella*, *Campylobacter*), sequential infections with multiple pathogens and host factors such as malnutrition (macro and micro-nutrient deficiency) and compromised immune system resulting in prolonged mucosal injury, poor intestinal repair and villous atrophy. Several other factors worsen the villi injury such as cow's milk protein allergy, carbohydrate and fat malabsorption (Flow chart 1).

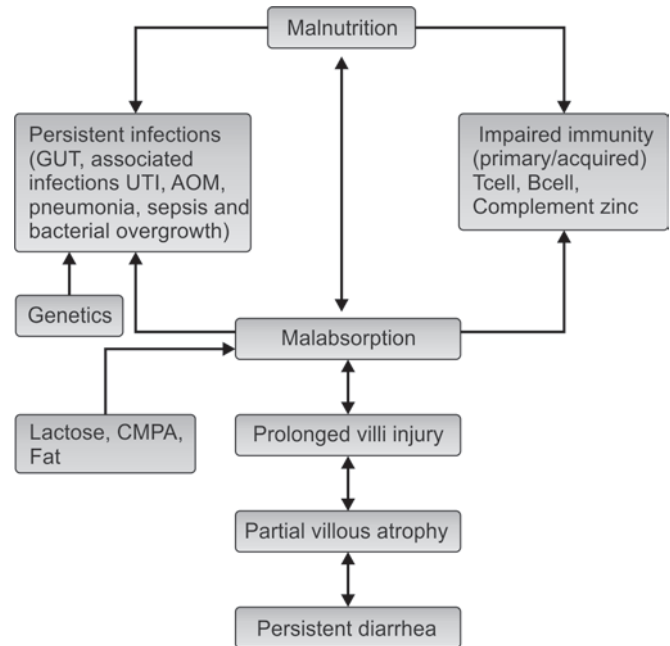

Enteric Infections

Globally, the most important underlying trigger for PD is an enteric infection and its associated sequel. Several pathogens such as bacteria, parasites and viruses have been implicated to cause prolonged or persistent diarrhea.

Bacteria

Shigella infections have been significantly associated with an increased risk of PD (age adjusted relative risk 1.83). Twenty-three percent of children with shigellosis had PD in a study from Bangladesh. Infection by antibiotic resistant *Shigella* isolates and occurrence of shigellosis in infants were observed to be risk factors for *Shigella* persistence.

Flow chart 1: Pathogenesis in persistent diarrhea

Other bacteria that have been associated are enteroaggregative *Escherichia coli*, enteropathogenic *Escherichia coli*, *Campylobacter*, *Salmonella enteritidis*, *Clostridium difficile*, *Aerobacter butzleri* and *Klebsiella* species.

Parasites

Giardia lamblia, *Blastocystis hominis*, *Cryptosporidium parvum*, *Entamoeba histolytica*, Strongyloidiasis, Coccidiosis and *Cyclospora cayetanensis* have been associated with prolonged and persistent diarrhea.

Viruses

Human immune deficiency virus, Human astrovirus 3, enterovirus and Picoberna viruses have all been linked with PD. Children with HIV infection have been reported to have an 11-fold increase in death from PD.

Multiple sequential infections lead to small bowel mucosal injury with blunting of the villi, cellular infiltration of the lamina propria and loss of epithelial barrier and absorptive functions which can persist even into adulthood. There are still major lacunae in the knowledge of the molecular mechanisms relating to the prolonged intestinal injury which is considered the central mechanism in the pathophysiology of PD of infectious etiology. The underlying enteropathy could be either due to a persisting inflammation following infection or due to persistence of the infection itself. In the latter situation, the bacterial effector molecules are translocated into the host cell which in turn downregulates the host immune system resulting in prolonged colonization and inflammation via altered toll-like receptor signaling. Activated macrophages, toll-like

receptor signaling and the microbiota influence the stem cell's response to injury but the potential role in the pathogenesis of PD remains uncertain. Intestinal regeneration is the important component of recovery and understanding this process will benefit in designing therapeutic interventions. Several host factors such as epidermal growth factor, interferon- γ and IL-8 play specific roles in different aspects of intestinal regeneration.

Malnutrition

The underlying nutritional status is an important determinant in the pathogenesis of PD (Fig. 1). Malnutrition causes various changes in small bowel such as partial or subtotal villous atrophy, decreased functional surface area, disrupted mucosal barrier, decrease in brush border enzymes, decreased secretory antibodies and mucins, altered intestinal permeability, decreased crypt cell turn over, decrease in intestinal hormones such as gastrin, CCK-PZ and gastric inhibitory polypeptides, altered motility and intestinal flora which may perpetuate and aggravate the problem. The functions of the pancreas and liver are also disturbed in malnutrition which further worsens the diarrhea. It has been well documented that malnutrition is a risk factor for diarrhea leading to prolongation of diarrheal episode and higher mortality. Children with low height for age Z scores are more prone for prolonged diarrhea which in turn results in further decline of height and weight for age Z scores indicating the vicious cycle of malnutrition- diarrhea-malnutrition. Micronutrient deficiencies such as zinc also share in the causative mechanism of poor intestinal repair. Vitamin A, iron, folate, iodine, selenium deficiencies have also been shown to contribute to the pathogenesis of PD by predisposing to infection, impairing the gut immunity and altering the gut permeability.

Fig. 1: Infant with severe malnutrition and PD
(For color version see plate 13)

Immune Mechanism

The role of immune deficiency in persistent diarrhea is not well understood. Malnutrition can depress the immune functions including cell mediated immunity, humoral immunity and complement function predisposing to recurrent gut infections that contribute to prolonged small bowel mucosal injury. Micronutrient deficiency itself may cause transient immune deficiency which could be an important risk factor for persistent diarrhea.

Genetics

There is considerable interest in the potential role of mannose binding lectin (MBL) in the pathogenesis of enteric inflammation. Monnose binding lectin deficiency is the most common form of immune deficiency and has been implicated in HIV and *Cryptosporidium* infections.

Cow's Milk Protein Allergy (CMPA)

During acute diarrhea there is an increased macromolecular uptake secondary to the mucosal injury. Children who are susceptible and are on animal milk protein feeds present with features of cow's milk protein allergy (CMPA). Acute enteritis, either initiates or magnifies antigen specific T-cell activation within the lamina propria. Continuing milk feeds further worsens the mucosal injury and perpetuates the diarrhea.

Lactose Intolerance

The cells on the tip of the microvillus containing the disaccharidases face the brunt of the attack during prolonged diarrhea. Malnutrition further interferes with the maturation of these absorptive cells as they move upwards from the crypt to the tips. Lactase which is proportionately less in each cell is affected the most, leading to secondary lactose intolerance.

This complex pathophysiology where all the factors have an important role to play needs to be understood for providing the best therapeutic intervention.

CLINICAL FEATURES

Children with persistent diarrhea warranting hospitalization are usually lethargic, apathetic, undernourished, with or without dehydration and generally fall below the 3rd weight percentile with height being less affected (Fig. 2). The skin may show changes of secondary zinc deficiency (acro-oro-genital dermatitis). Very sick children may present with conjunctival xerosis, glossitis, cheilitis, stomatitis and features of hypoproteinemia (edema). Detailed examination of all systems should be done to exclude otitis media, pneumonia and any other source of sepsis. An enlarged liver may indicate fatty infiltration.

Table 1: Investigations in persistent diarrhea

<i>Initial tests</i>	<i>Additional tests</i>	<i>Specialized tests</i>
Full blood count including ESR, CRP, urine microscopy, stool for reducing substance, parasites and occult blood	Tissue transglutaminase antibody	Upper GI endoscopy with duodenal biopsy
Liver function tests, blood urea, serum creatinine, sugar, electrolytes	Immunoglobulin profile, HIV ELISA	Ileocolonoscopy
Urine and blood culture	Cow's milk protein antigen	Duodenal electron microscopy
Mantoux and X-ray chest	Ultrasound abdomen	

CONSEQUENCES OF PERSISTENT DIARRHEA

Unlike the morbidity and mortality in acute diarrhea occurring secondary to dehydration and dyselectrolytemia, a different spectrum of problems are seen in PD. The major and disturbing consequences are growth faltering, worsening of malnutrition, impairment of cognitive functions and increase in mortality and morbidity during the subsequent diarrheal or nondiarrheal diseases.

INVESTIGATIONS

Children with persistent diarrhea need to be extensively investigated for proper and effective management (Table 1). The initial investigations should include complete blood count including ESR, stool microscopy and occult blood, urine routine, urine and blood for culture, blood sugar and urea, serum electrolytes, C-reactive protein, creatinine, liver biochemistry, Mantoux and X-ray chest. The next set of investigations include tissue transglutaminase antibody, HIV and immunoglobulin profile to identify any other probable etiology. Upper GI endoscopy with duodenal biopsy and colonoscopy are done if there is occult blood positivity in stools, protein losing enteropathy and any suggestion of an inflammatory bowel disease. In young infants with a diagnosis of protracted diarrhea electron microscopy of the duodenal mucosa may help in identifying congenital villi disorders.

DIFFERENTIAL DIAGNOSIS

In certain situations, it may be very difficult to exclude conditions listed under chronic diarrhea or protracted diarrhea of infancy since all the three share some similarities. Congenital villi disorders such as autoimmune enteropathy, tufting enteropathy, IgA deficiency, sucrase isomaltase deficiency, acrodermatitis enteropathica and secretory tumors should be considered.

MANAGEMENT OF PERSISTENT DIARRHEA

The cornerstone of management in PD is to provide nutritional support and ensure proper rehabilitation with an objective to restore intestinal function and improve the weight and growth of the child. Therapy is based on a

combination of appropriate fluids to prevent or treat dehydration, nutritious diet that does not aggravate the diarrhea, essential vitamins and minerals and antimicrobials to treat infections. Some children need to be hospitalized specially if they are young infants, dehydrated, severely malnourished or have systemic infections. The treatment of persistent diarrhea can be divided into three phases:

- Phase of resuscitation
- Phase of renourishment
- Phase of rehabilitation.

Phase of Resuscitation

During this phase, the child is assessed regarding hydration status and fluids administered according to the degree of dehydration (no/ some or severe) as plan A, B or C. Associated nonintestinal infections such as pneumonia, sepsis, urinary tract infection, and otitis media should be treated according to standard guidelines. Enteral infections such as amebiasis or giardiasis should be treated with metronidazole. When *Shigella* is isolated it can be treated with ciprofloxacin or ceftriaxone. Children with cholera can be treated with doxycycline or erythromycin. Antifungals may be necessary in the presence of oral candidiasis. Routine treatment with antimicrobials is not effective and should not be given. Blood and blood products need not be administered routinely. If the hemoglobin is less than 4.5 gm/dl packed RBC may be advised.

Phase of Renourishment

The mainstay of therapy of persistent diarrhea is dietary management.

Infants Aged Less than 6 Months

Breast milk should be continued for infants on mother's milk. Since PD is rare in children who are exclusively breastfed, mothers who are not breastfeeding their wards are encouraged to re-establish lactation. The majority of children with PD have some degree of lactose intolerance and infants who are on artificial milk can be offered low (2.5-5 gm/kg/day) lactose feeds such as yogurt. If there is no improvement in 2 days the infant requires a lactose free diet.

Table 2: Diet in persistent diarrhea

<i>Plan A: Low lactose diet</i>	<i>Plan B: Lactose free diet</i>	<i>Plan C: Lactose + sucrose free diet</i>
Sugar: 1½ tsp	Glucose: 1½ tsp	Glucose: 1½ tsp
Oil: 1 tsp	Oil: 1½ tsp	Oil: 1½ tsp
Puffed rice powder: 2 tsp	Puffed rice powder: 3 tsp	
	Egg white: 10 tsp or Moong dhal 1 tsp	Chicken puree: 5 tsp
Water: 100 ml	Water: 120 ml	Water: 150 ml
Calories/100 g: 85 kcal	Calories/100 g: 90 kcal	Calories/100 g: 67 kcal
Proteins/100 g: 2 g	Proteins/100 g: 2.4 g	Proteins/100 g: 3 g
Mix milk, sugar and rice. Add boiled water and mix well. Add oil. Feed the child	Whip egg white well. Add rice, glucose, oil and mix well. Add boiled water and mix rapidly to prevent clumping. If moong dhal is added cook on low fire. Feed the child.	Boil chicken remove the bones and make chicken puree. Mix glucose and oil. Add boiled water and make a smooth paste. Feed the child.

For Infants >6 Months and Young Children

Simple disaccharide intolerances are very common and need minimal dietary intervention. Food prepared with cereals, pulses and curd are best suited for children above six months of age. Breast milk if available is continued and supplemented with standard diets which are prepared from home available ingredients. If breast milk is not available lesser quantity 50 to 60 ml/kg/day of milk to provide 2.5 to 5 gm/kg/day of lactose is offered along with cereals and MCT oil (plan A). Rice is the best cereal and rarely associated with allergy. About 65 to 75 percent of children will improve on this diet. These milk cereal mixtures are highly palatable, provide good quality protein micronutrients and result in good weight gain. In 10 to 15 percent of children who cannot tolerate even low lactose diet, feeds may be substituted by an equally protein energy dense lactose free diets (plan B) as shown in Table 2. Studies have shown that children who have been fed on cereal milk mix in which 35 percent of the calories was provided by milk had significant weight gain than those children on isocaloric milk free cereal based feed. Diets can be designed using one source of carbohydrate (rice, potato, broken wheat, semolina, corn), protein (Bengal gram, casein, green gram, chicken and egg) and fat (any oil preferably coconut oil) besides vegetables and fruits to provide micronutrients. It is ideal to continue low lactose or lactose free diet for at least a couple of weeks before reintroducing milk slowly. A small proportion of children (less than 5%) have to be managed with no lactose, sucrose or maltose diet such as chicken-based diets (plan C) and a very small proportion may require parenteral nutrition.

Principle of Feeding

The energy density of feeds should be around 1 kcal/g with an aim to provide an energy intake of at least 110 kcal/kg/day which is gradually increased to 150 kcal/kg/day with

Table 3: Micronutrient supplementation

Micronutrient supplement: Give for at least 2 weeks

Vitamin A: Oral; <6 months: 50,000 U; 6-12 months: 1 lac unit

Vitamin K: Single dose, 5-10 mg, IM or IV route

Zinc: 2 mg/kg/day

Iron 3 mg / kg/ day is added once child tolerates

Folic acid: 5 mg on day 1 and then 1 mg/day

Copper: 0.3 mg/kg/day

Severe malnutrition: Add Inj magnesium sulfate (50%) 0.2 ml/kg/dose BID × 2 days

a protein intake of between 2 to 3 g/kg/day. Vegetable oil is also added to the diet to provide calories and improve taste and the child is given 6 to 7 feeds per day to provide adequate calories. If the child improves on this diet, it is advisable to continue the same for one more week before switching to regular home available food. Hospitalization is recommended if child does not improve.

Micronutrient Supplementation

It is ideal to provide micronutrients through natural sources but initially it may not be practical and therefore vitamins, iron and zinc may be supplemented through oral medications. The current micro/macronutrient supplement is shown in Table 3. Iron is essential and is given at 3 mg/ kg/ day once child tolerates medications.⁵

Treatment Failure

The criteria for change of diet in the absence of any other predisposing factor such as recent infection are: (1) reappearance of dehydration any time after stabilization (2) Increase in number of stools >6/day (3) No weight gain after 3 days of adequate caloric diet >100 gm/kg/day or

weight loss. A diet from one plan should be given for a minimum period of seven days before changing the plan unless treatment failure occurs earlier.

Successful Treatment

The criteria for classifying success include: (i) Decrease in the frequency of stools (<2 loose stools/ day for 2 consecutive days) (ii) Adequate oral intake (iii) Weight gain (iv) Defervescence of fever.

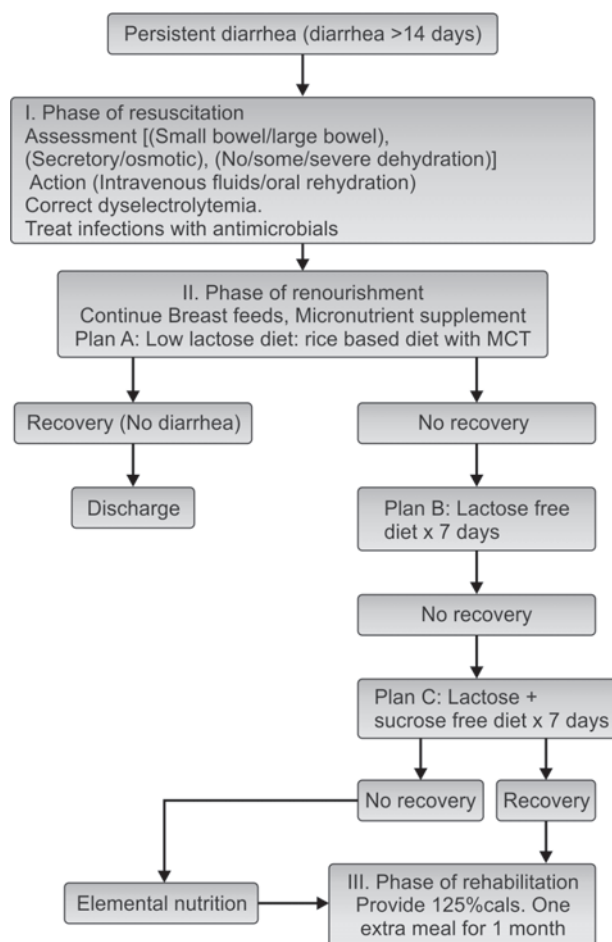

Treatment of Severely Malnourished Child with Persistent Diarrhea

Dietary management is more complicated when the child has PD with severe undernutrition, sepsis and dehydration. These children do not tolerate full enteral feeds and may need judicious balance of enteral and parenteral supply of nutrients till sepsis is cleared and the child's GI tract is ready for full oral alimentation. Albumin infusions may be required if there is significant hypoproteinemia. Simple PPN solutions incorporating additional glucose and amino acid preparations may suffice. Oral alimentation is initiated as early as possible to help villi repair. Nasogastric slow continuous carbohydrate-based feeds with low protein may be given initially and proteins slowly increased till the daily requirement is attained. Medium chain triglycerides are excellent source of energy. Monosaccharides and commercial lactose free are avoided till bowel frequency comes down to <4/day. The treatment protocol for persistent diarrhea is shown in Flow chart 2.

Commercially Available Lactose and Sucrose Free Diets

Many casein or soybean protein-based proprietary preparations with maltose and maltodextrins are available in the Indian market which can be offered to children with PD once the consistency and frequency of stools improve (Table 4). These are recommended when there are practical difficulties and preparations cannot be made at home.

Flow chart 2: Treatment protocol for persistent diarrhea

Children with persistent diarrhea generally do not need specialized elemental formulae. Occasionally partial or extensively hydrolyzed protein diets and elemental diets, are required which may overcome the usage of parenteral nutrition.

Table 4: Commercially available formulas that may be beneficial in persistent diarrhea

Commercially available formula	Composition	Energy (per 100 g)	Protein (per 100 g)
Isomil	Milk free+ lactose free	496 kcal	13 g
Nusobee casein	Lactose free	472 kcal	16 g
Zerolac	Lactose free+ sucrose free	472 kcal	15 g
Nusobee soy	Lactose free+ sucrose free	480 kcal	15.6 g
Prosoyal	Lactose free+ sucrose free	488 kcal	14 g
Simyl MCT	Lactose free+ sucrose free	456 kcal	14 g
Neogain	Hypoallergenic, gluten free, chicken-based formula	372 kcal	10 g
Neocate	Hypoallergenic milk protein free, amino acid formula	475 kcal	13 g

Food Allergies

Cow's milk protein allergy seen in two to three percent of children is the most common food protein allergy which can either cause or perpetuate diarrhea. In India, it has been reported in 13 percent of children less than 2 years of age presenting with chronic diarrhea. Rarely allergens in egg, soy, wheat, peanut, tree nuts, fish and crustaceans may cause diarrhea though their incidence is extremely rare in infantile PD. In some children with CMPA, it is necessary to substitute feeds with hypoallergenic feeds. These costly special commercial formulae are produced through enzymatic hydrolysis of bovine casein or whey, which are further processed by heat treatment and/or ultrafiltration. They are classified as 'extensively' or 'partially' hydrolyzed formulae according to the degree of protein hydrolysis. Partially hydrolyzed milk is more acceptable than extensively hydrolyzed milk since it retains some milk taste. Majority of children with CMPA outgrow it by 3 years of age.

Phase of Rehabilitation

Close supervision of nutrition during the period of convalescence is very important since relapses are common. Catch up growth is as important as cessation of stools and therefore at least 125 percent of calories are provided until the ideal target is reached. This can be achieved by providing one extra meal for 2 weeks after every episode of acute diarrhea and for one month following PD. This practical simple advice will help in the nutritional rehabilitation.

PREVENTION OF PERSISTENT DIARRHEA

Since the pathophysiology of PD is still not clear, it is difficult to either determine the frequency with which PD follows a primary enteric infection or design interventions during the acute diarrheal illness. Certain preventive measures such as appropriate feeding (breast and complementary feeding) and diligent attention to environmental hygiene and sanitation will go a long way in preventing PD in a community. In addition, apart from malnutrition, there are some well recognized risk factors in children, such as diarrhea in infants less than 3 months of age, absence of breast milk, recurrent diarrhea, antibiotic polypharmacy, early introduction of animal milk, lactose intolerance, micronutrient deficiency, associated infections like urinary

tract infections, chronic suppurative otitis media and bronchopneumonia and diarrhea due to enteroaggravative *E. coli*, *giardia* and *cryptosporidium*. These factors if attended to promptly or prevented could decrease the progression of acute diarrhea to PD. Measures such as exclusive breastfeeding till the age of 6 months, avoiding early introduction of animal milk protein and antibiotic over usage, safe complementary feeding strategies, optimal management with improved oral rehydration, zinc supplementation and continued feeding during acute diarrhea are definitely beneficial in preventing PD. The extent to which prevention of infectious diarrhea by vaccine will reduce PD and malnutrition is not known.

Recent additional strategies for preventing, treating and enhancing recovery from diarrhea and PD include the use of probiotics and functional foods. Genetically engineered molecules such as butyrate have been recommended for treatment for shigellosis by the upregulation of cathelicidin an antimicrobial peptide of the innate immune system. Isoleucine and vitamin D also appear to induce these antimicrobial peptides however more work is necessary in this field.

Persistent diarrhea with its associated high morbidity and mortality is therefore still a social and economic burden to the family, community, nation and globally. Though progress has been made in the management in the form of adequate resuscitation and good nutritional support more research is necessary in understanding the pathophysiology and prevention.

Dietary Management of Celiac Disease

Sarath Gopalan, Neelanjana Singh

Empowering any person diagnosed with celiac disease to lead a normal healthy life on a gluten free diet is the ultimate objective of both the physician and the dietician. In order to achieve this objective, the glutenfree diet (GFD) should provide the recommended dietary allowance (RDA) of both macro- and micronutrients, specific to that age group. In general, the aim is to provide 4 to 8 servings of gluten free cereal, 2 to 3 servings of milk/soy milk/cheese/curd, 2 to 3 servings of legumes/dal, 3 to 5 servings of fresh vegetables, 2 to 4 servings of fruit, 2 to 3 serving of egg/fish/poultry, a handful of nuts (30g), 4 to 6 teaspoon fat.

Once the diagnosis of celiac disease has been made, the real challenge begins. From then on, the patient is expected to interact regularly with the dietician/clinical nutritionist. In the early stages, the clinical nutritionist has the additional very important task of being entrusted with the responsibility of providing emotional support to the family along with diet counseling of the affected individual. This can be a daunting task as the average north Indian family is emotionally shattered when they are told that wheat has to be eliminated from the diet for the rest of their life in order to treat this problem. Lifelong exclusion of wheat, rye, barley and their products is the only form of treatment for celiac disease. *It is extremely important to convey to the patient at the outset that despite the restrictions that are mandatory, such patients can consume a balanced diet with a variety of foodstuffs from all the major food groups.* In almost hundred percent of the cases, by the time the diagnosis is established, the patients are nutritionally challenged due to malabsorption of nutrients that has occurred over a period of time. However, remarkable recovery occurs quite rapidly in most cases (changes in body weight may be demonstrable in 6-8 weeks).

ENSURING COMPLETE ADHERENCE TO A GLUTEN FREE DIET

Lifelong exclusion of gluten is the prescribed treatment of celiac disease. It is extremely important to explain to the family that the GFD needs to be continued even if the patient appears to have been cured and remains asymptomatic. Cereals form the bulk of the diet in all parts of our country. In the northern and the western parts of our country where wheat is the dominant cereal in all meals the switch to a gluten free diet may require major modifications. A few of the cereals that can be safely used in a GFD plan are water chestnut (Singhara), amaranth (Ramdana), arrowroot (Paniphal), buckwheat (Kuttu), corn (Makki), millets (Ragi, Bajra, Jhangora), quinoa, rice, sago, sorghum (Jowar), tapioca (Shimla alu). Besan, soyabean and legumes can also be safely used as flours in combination with the above cereal flours to give the right texture, elasticity and taste to the “rotis” that are safe and acceptable for individuals with celiac disease. The acceptability of these alternate flours is satisfactory only if the ratios of the suggested flours prescribed by the dietician are adhered to. Failing to follow these instructions may have the “rotis” becoming very dry and brittle, which makes it difficult to knead, roll and cook. Moreover such dry “rotis” are disliked and not accepted by most children. The freedom to use fats in the diet of patient with celiac disease comes is very useful in such a situation. Any of the healthy fat sources can be added to the bread to improve palatability and the energy value of the food. Similarly, many of the gluten free flours require addition of warm water and butter/cream during the kneading process to make the “rotis” soft and edible.

The role of oats in celiac disease deserves special mention owing to the controversy surrounding it. The storage protein in oats is avenin which is not toxic to most individuals with celiac disease. However, the commercial

oats available in India is not gluten free. Gluten is a contaminant from other gluten containing grains, i.e. wheat, rye and barley that are usually grown alongside the wheat crop.

PROCESSED FOODS, THE BANE

The real challenge of adhering to a gluten free diet arises when processed packaged food forms an integral part of the diet, as is usually the case in children. A few examples would explain the intricacies that are involved in processed food ingredients. Baker's yeast is a gluten free product but brewer's yeast is not. Therefore, gluten free flour bread that uses brewer's yeast will be contraindicated in any individual with celiac disease. Similarly, there are many varieties of soy sauce, some of which are fermented using a wheat source. Such soy sauces could be one of the ingredients in the making of other sauces such as teriyaki, Pesto or oyster sauce rendering these products unsafe for patients with celiac disease. Rye is a cereal used for making bread in many Western countries in the developed world and many individuals in India mistake *Rai* seeds used extensively in India as seasoning and as a paste for the cereal rye. The cereal rye is on the 'unsafe list' whereas *Rai* seeds are safe. Most pure spices are gluten free, but when processed, changes in the composition, as in the case of *Hing* (Asafoetida), wheat flour is added to "*Hing*" rendering the product unsafe for use by individuals with celiac disease. Yet another example is the case of malt vinegar and synthetic vinegar. While malt vinegar contains gluten, the synthetic version is safe for use. Therefore, it may be possible for a product to be gluten free to begin with, but the method of manufacturing has a lot to do with the safety of the final product. For example, corn is a safe cereal but cornflakes, which are malted, become unsafe. Many medicines and cosmetic products could also contain gluten in the form of wheat germ oil or bulking agents, thus posing risk to affected individuals.

Many patients fail to understand the gravity of the problem when diagnosed with disease. Quite often, not just children but even adult patients comply poorly and ingest gluten containing foods intermittently. Such poor compliance not only retards recovery but also poses other risks such as stunting and neurological problems both in children and in adults. In untreated or partially treated celiac disease, malabsorption of calcium and vitamin D and iron could lead to osteoporosis and anemia. Celiac disease left untreated could also lead to serious problems such as cell mutation and malignancy. Providing intensive and repeated sessions of counseling is the only way of ensuring strict adherence to the diet. It is also extremely helpful if the family is provided complete information regarding availability of glutenfree products in the neighborhood. It is also feasible to make many glutenfree products at home with safe ingredients without straining the

family's financial resources. It is not mandatory to purchase expensive gluten free products in order to provide the appropriate nutritional support to patients with celiac disease. Locally available, inexpensive food items prepared in a safe work area are equally effective.

Reading food labels, understanding the hidden sources of gluten and the possible mechanisms of cross-contamination are issues to be discussed with the family in detail during the counseling sessions. The use of common toasters and roti containers and common oil for deep-frying all kinds of foodstuff are common pitfalls that occur when following a gluten free diet. Being alert to the various other sources of contamination such as chopping boards, knives, dusters is just as important when following a gluten free diet. Family members are made aware of strategies that help cope with events such as birthday parties and when eating out.

Until recently, celiac disease was considered a disease occurring in the Western world. Emerging epidemiological data from India, though scanty show a prevalence of 1 in 96 persons (Makharia et al, *J Gastroenterol Hepatol*, 2011). Celiac disease, initially thought to be exclusively a pediatric entity, is now known to occur at any stage in life beyond 6 months of age to even 90 years of age. The clinical presentation of the disease is varied and could involve 'atypical' presentations which are not restricted to symptoms suggestive of celiac disease associated with predominant gastrointestinal symptoms. The atypical presentation may involve skin manifestations in the form of a rash. In the 'silent' form of presentation the symptoms could be as nonspecific as feeling of fatigue or peripheral neuropathy with or without growth failure. Some of the recent research seems to suggest that dental enamel defect which is yet another manifestation of celiac disease could help identify with this problem and send them to a specialist for treatment. The varied clinical presentation of this disease is one of the reasons why diagnosis is delayed in many cases. The clinical suspicion of celiac disease should prompt the treating physician/clinical nutritionist to screen for the disorder using serological methods IgA tissue transglutaminase (tTG) antibody or IgA Endomysial antibody (EMA). The confirmation of the diagnosis is through an endoscopically obtained duodenal mucosal biopsy which shows histological features characteristic of celiac disease.

It is true that currently the only treatment option available for a celiac patient is to avoid all products derived from wheat, rye and barley. However, some of the experimental treatment options are showing promise. One such modality that is being tested is the use of enzyme combinations that can detoxify gluten before it enters the small intestine. Yet another method is scavenging the gliadin by using an appropriate binder. This would prevent the digestion of gliadin in the gastrointestinal tract. Other 'adjunctive' therapies such as the use of hookworm (*Necator*

americanus) are some of the nondietary approaches being tested for celiac disease. It seems possible that some of this experimentation and research will bear fruit and make a difference to the patient.

Neelam Mohan, Vikram Kumar

INTRODUCTION

The role of microbes in the health of human gut has been well documented. Their presence in the gut protects the body from pathogenic organisms. Efforts to optimize the intestinal microbial milieu have increased the interest in adding probiotics and prebiotics to nutritional products. The use of probiotics and prebiotics should be backed by evidence based medicine.

DEFINITION

Probiotic: An oral supplement or a food product that contains a sufficient number of viable microorganisms to alter the microflora of the host and has the potential for beneficial health effects.

Prebiotic: A nondigestible food ingredient that benefits the host by selectively stimulating the favorable growth and/or activity of 1 or more indigenous probiotic bacteria.

Synbiotic: A product that contains both probiotics and prebiotics. Evidence for synergy of a specific prebiotic for a probiotic in the product is not essential. Synbiotics may be separate supplements or may exist in functional foods as food additives.

Postbiotic: A metabolic byproduct generated by a probiotic microorganism that influences the host's biological functions.

Functional food: Any modified food or food ingredient that provides a health benefit beyond that ascribed to any specific nutrient/nutrients it contains. Any food that contains probiotics or prebiotics is a functional food, e.g. yogurt and human milk.

PROBIOTICS

These bacteria are fermentative, obligatory, or facultative anaerobic organisms and are typically nonmotile and

produce lactic acid. These include members of the genera *Lactobacillus*, *Bifidobacterium*, and *Streptococcus*. In the human digestive tract, these organisms predominate in number and do not allow potential pathogenic microorganisms to inhabit and grow. It is currently hypothesized that these microbes generate small molecular metabolic byproducts which may function biologically as immune modulators. *Lactobacillus rhamnosus* GG (LGG), *Bifidobacterium lactis*, *Saccharomyces boulardii* and *Streptococcus thermophilus* are the most studied probiotic bacteria. Recently, some yeasts and their byproducts have also been studied and have been frequently used as probiotics.

PREBIOTICS

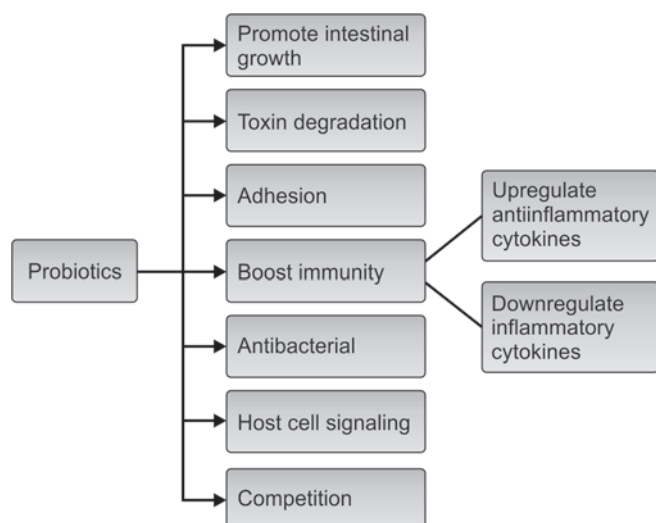

Prebiotics usually are naturally occurring indigestible oligosaccharides which may be added as dietary supplements to foods, beverages, and infant formula. In the presence of these prebiotics there is enhanced proliferation of probiotic bacteria. Examples of prebiotic oligosaccharides include fructo-oligosaccharides (FOSs), inulin, galacto-oligosaccharides (GOSs), and soybean oligosaccharides. The dietary fiber and dietary nucleotides although do not fit the exact definition of a prebiotic but have shown to have immunomodulating and direct intestinal biological properties.

MECHANISM OF ACTION OF PROBIOTICS (FLOW CHART 1)

An infant at the time of birth has a sterile gastrointestinal tract, but bacterial colonization occurs rapidly. The intestinal bacterial colonization is affected by gestational age, mode of delivery and diet. There is delay in those born by cesarian delivery, born preterm, and/or exposed to perinatal or postnatal antibiotics.

The composition of intestinal microflora does not change significantly after infancy. The intestinal microflora is important to the host for several reasons:

Flow chart 1: Mechanism of action of probiotics

- Microflora benefits the host by increasing colonization resistance (preventing overgrowth of potentially pathogenic organisms).
- Intestinal flora has a metabolic activity similar to that of the liver.

Probiotics and prebiotics are believed to exert positive effects on the development of the mucosal immune system. It is also believed that exposure to pathogenic microorganisms, lifestyle, illness and antimicrobial agents in the childhood may result in immune dysregulation in susceptible individuals and may lead to some chronic disease states.

The concept of treatment with probiotics comes from a belief that modern humans do not consume or replenish the beneficial microbes in their bodies and that they can do so by consuming probiotics.

Historically, ingested probiotic strains were believed to:

- Adhere to the gut wall,
- Block pathogen adhesion and growth and
- Give a nonspecific boost to immunity

It has been suggested that probiotics have other functions like producing anti-infectives, such as hydrogen peroxide and bacteriocins. They are also assumed to stimulate the cell signals that strengthen host-cell mucus barriers against pathogen invasion; and other signals that prevent virulent factors, such as toxins, from being released and maintaining balance of the TH1/ TH2 system.

USE OF PROBIOTICS IN CURRENT CLINICAL PRACTICE (TABLE 1)

Acute Infectious Diarrhea

Published randomized controlled trials (RCTs) in preventing acute gastrointestinal tract infections with the use of probiotics in healthy infants and children have

Table 1: Recommendations for probiotic use

Clinical condition	Effectiveness
Diarrhea	
Infectious childhood—treatment	A
Prevention of infection	B
Prevention of AAD	A
Prevention of CDAD	B
IBD	
Pouchitis—Preventing and maintaining remission	A
Ulcerative colitis, Crohn's	C
IBS	
	B
Allergy	
Atopic eczema associated with cow's milk allergy	A
NEC	
	C
<i>H. pylori</i> eradication	No efficacy

shown modest benefit. The results of a meta-analysis of probiotic prevention of acute rotavirus gastroenteritis in child care centers indicated that approximately 7 children would need to have been given LGG to prevent 1 child from developing nosocomial rotavirus gastroenteritis. To date, the available data do not support routine use of probiotics to prevent nosocomial rotavirus diarrhea in child care centers. However, there may be special circumstances in which probiotic use in children in long-term health care facilities or in child care centers is beneficial.

In a randomized, double-blind, placebo-controlled trial, administration of LGG significantly shortened the duration of acute rotavirus diarrhea by a mean of 40 hours, but duration of diarrhea of any other etiology was not affected. Probiotic administration also shortened the time necessary for intravenous rehydration by a mean of 18 hours. Results of several other meta-analyses and a Cochrane review 1 indicate that probiotics reduce the number of diarrheal stools and the duration of the diarrhea by approximately 1 day. The best results were observed with *Lactobacillus* GG. No obvious adverse effects of the probiotics were reported. Clinical and statistical heterogeneity of the prophylactic interventions precluded drawing clear conclusions about the efficacy of probiotics in prevention of acute infectious gastroenteritis.

Clostridium Difficile Associated Antibiotic Associated Diarrhea

Several open studies have suggested that *Saccharomyces boulardii*, *Lactobacillus* GG and *Lactobacillus plantarum* LP 299v could be beneficial in CDAD. However, larger controlled studies have not been performed in children. A randomized placebo controlled trial of *S. boulardii* plus standard antimicrobial therapy in adult patients with

recurrent CDI showed a risk reduction of recurrence down to 34.6 percent as compared to 64.7 percent in placebo group. In a recent study, Szajewska et al, gave the first demonstration of the efficacy of *Saccharomyces boulardii* in a double-blind, placebo-controlled trial in infants. Patients receiving *Saccharomyces boulardii* had a lower prevalence of AAD (AAD decreased by 81%) compared with patients receiving the placebo.

In an open study 19 infants and children presenting with a clinical picture of chronic diarrhea and in whom toxigenic *C. difficile* was the only enteropathogen identified by stool culture and stereotyping were evaluated. Most of the patients have been given one or more courses of antibiotics for intestinal infections in the weeks or months proceeding admission. Treatment with *Saccharomyces boulardii* at a dosage of 500 to 1000 mg/day (depending on age) for 15 days led to a rapid regression of the symptoms in 18 of the children, and clearance of toxin B and *C. difficile* in 16 of them.

Antibiotic-Associated Diarrhea

The antibiotics with which AAD is commonly associated are; Penicillin G and V (3%), Penicillin A and M, amoxycylav, cephalosporins, macrolides, trimethoprim-sulphamethoxazole and erythromycin.

There are 3 meta-analyses involving only children: The first review (December 2005) identified 6 RCTs involving 766 children. The review found that the treatment with probiotics compared with placebo reduced the risk of AAD from 28.5 to 11.9 percent. The second (August 2006 and the third meta-analysis or Cochrane review were by the same authors. They included 10 RCTs, (6 of them were included in the first review) involving 1986 children comparing treatment with lactobacilli species, bifidobacterium species, *Streptococcus* species or *Saccharomyces boulardii* alone or in combination.

The summary of the Cochrane review is as follows:

- Probiotics seem to have a positive effect on the incidence of diarrhea that is their use prevented AAD.
- However, once the AAD was set in the mean duration of diarrhea and stool frequency was no different with the use of probiotics versus controls.
- 5 of the 10 trials reported adverse events and there was no increase in adverse events with the use of probiotics.
- The probiotic strains that were found to be most effective were *Lactobacillus* GG and *Saccharomyces boulardii*.
- The studies were divided into 2 groups, namely ≥ 5 billion CFU of probiotics/day, and <5 billion CFU probiotics/day.
- It was seen that the probiotic dose of >5 billion CFU/day had a significant impact in preventing the incidence of AAD as compared to the dose of <5 billion CFU/day.

Traveller's Diarrhea

The use of probiotics for this disease remains controversial. The main advantage of probiotic therapy in TD that is mediated through changes in intestinal microflora in response to exposures incurred during travel is that they are therapeutically effective without disrupting the re-establishment of the normal protective intestinal microbial flora.

The conclusion drawn from an important meta-analysis was that several probiotics (*Saccharomyces boulardii* and a mixture of *Lactobacillus acidophilus* and *Bifidobacterium bifidum*) are safe and effective for the prevention of TD. No serious adverse reactions were reported. Probiotics may offer a safe and effective method to prevent TD.

Efficacy was also observed to be influenced by travel destination in several trials—the rate of TD observed in tourists from developed countries administered *Saccharomyces boulardii* who travelled to Africa was reduced by 50 percent whereas in those who travelled to India, there was no protection.

ATOPIC DISEASES

Probiotics have been shown to reduce inflammatory cytokines and intestinal permeability *in vitro*. Such an effect would be beneficial in allergic disorders. Therefore, several studies have looked at the efficacy of probiotics in allergic conditions, such as eczema, allergic rhinitis and food allergies. The results of these studies are promising, but a definitive role is yet to be confirmed. When *Lactobacillus* GG or placebo was given to pregnant mothers with a strong family history of eczema, allergic rhinitis or asthma and to their infants for the first 6 months after delivery, the frequency of developing atopic dermatitis in the offspring was significantly reduced at 2 and 4 years. Another placebo-controlled study showed significant improvement in children with atopic dermatitis after a 6-week administration of *L. rhamnosus* 19070-2 and *L. reuteri* DSM 122460. Children with high immunoglobulin E levels and 1 or more positive skin tests were more responsive to probiotic therapy. Infants with atopic eczema and cow's milk allergy responded more effectively to hydrolyzed whey formula when *Lactobacillus* GG was added in a large controlled study. When *L. paracasei* was given for 30 days to 80 children with perennial rhinoconjunctivitis, the quality of life questionnaire scores significantly improved relative to placebo. However, *L. rhamnosus* supplementation failed to show any benefit in birch-pollen allergic children in placebo-controlled trial. In a 2008 Cochrane review, probiotics have not yet been proven to be effective in the treatment of eczema.

CHRONIC INFLAMMATORY BOWEL DISEASE

In theory, probiotics may be beneficial in the treatment of IBD. It has been proposed that in individuals with

genetic susceptibility to IBD, chronic inflammation occurs in response to commensal digestive microflora because of various inherited defects of innate inflammatory-response pathways. Hence, modulating the commensal intestinal bacterial environment with probiotic supplements may reduce the inflammatory response in patients with IBD.

CHRONIC ULCERATIVE COLITIS

Evidence-based research suggests that probiotic therapy, either alone or along with an adjuvant, may be an effective alternative for some UC patients. The research does not definitively state that probiotic therapy is beneficial for either active disease or maintaining remission. Clinical trials suffer from small sample sizes, a noticeable lack of controls, and inconsistent results. The first pediatric RCT on the use of VSL#3 with standard IBD therapy showed promising results both in indication and maintenance of remission. However, the numbers were small. Future studies could examine the appropriate dosing, the effect of different formulations on probiotic efficacy, and a formalized safety testing strategy to assess novel bacterial strains for probiotic therapy.

Pouchitis is the most frequent long-term complication following pouch surgery for ulcerative colitis. The etiology is unknown, but an increased gut bacterial concentration is one of the main risk factors. The rationale for using probiotics in pouchitis is based on evidence implicating intestinal bacteria in the pathogenesis of this condition.

VSL#3, a highly concentrated mixture of probiotics, has been shown to be effective in the prevention of pouchitis onset and relapses and may be helpful in patients with mildly active pouchitis. It should be noted that the beneficial effect of one probiotic preparation does not imply efficacy of other preparations containing different bacterial strains, because each individual probiotic strain may well have unique biological properties.

CROHN'S DISEASE

Recent RCTs in which probiotics were used in pediatric as well as adult patients with Crohn's disease resulted in no significant benefit. A recent Cochrane review indicated that there is, as yet, no proven benefit for maintaining remission by administering probiotics to adults with Crohn disease.

IRRITABLE BOWEL SYNDROME AND CONSTIPATION

A number of studies have evaluated the response of irritable bowel syndrome to probiotic preparations. Although results between studies are difficult to compare because of differences in study design, probiotic dose, strain and duration of therapy, some studies suggest symptom

improvement. There are 9 randomized and 2 open studies in adults, whereas there is only 1 randomized pediatric study. Ten of the 12 studies report amelioration of symptoms such as bloating, abdominal pain or colonic transit. Many of the studies were fairly short and do not reflect improvement in the quality of life.

NECROTIZING ENTEROCOLITIS

Necrotizing enterocolitis (NEC) may result from an absent intestinal microbial colonization. Recently, a systematic review with meta-analysis or randomized controlled clinical trials has been published. The authors aimed to review all randomized controlled trials, evaluating efficacy as well as safety of any probiotic supplementation, in preventing stage 2 or greater NEC in preterm neonates (gestation <33 weeks) with very low birth weight (<1500 g), started within the first ten days, with a duration of at least seven days. Only 12 were randomized well-controlled clinical trials in preterm infants and five studies were excluded from the meta-analysis data regarding the NEC due to sepsis mortality and feeding practices. The results of the analysis are quite promising. A higher proportion of neonates in the control group developed definite NEC (38 of 690, 6%), compared to the probiotic group (15 of 730, 2%). Meta-analysis of data reduced risk of NEC in the probiotic group.

PROBIOTICS IN *H. PYLORI*/INFECTION

Role of probiotics in preventing the acquisition of *H. pylori* infection in uninfected subjects has not been investigated formally. A recent study indicates that the effectiveness of an eradication therapy regimen can be enhanced by using probiotics. A recent open, prospective trial undertaken in Italy showed that a mixture of nine probiotics and bovine derived lactoferrin and inulin, as a prebiotic, increased the success rate of eradication to 89 percent compared to just 72 percent compared to those treated with triple therapy alone for 7 days. One prospective, randomized, and controlled study assessed the success of triple therapy given for 7 days together with unfermented pasteurized milk, compared with the same triple therapy regimen and 1010 colony-forming units of *L. casei* DN-114 001 given once daily, in 100 mL of fermented milk, for 14 days. Triple therapy alone (57.5%) was less successful than triple therapy and probiotic (84.6%) in eradicating *H. pylori* infection. By contrast, another study evaluating *H. pylori*-infected children living in Argentina reported no benefit of adding yoghurt.

USE OF PREBIOTICS IN PREVENTION AND TREATMENT OF CLINICAL DISEASES

Few RCTs have evaluated the use of prebiotics in preventing or treating specific childhood diseases.

Prevention and Treatment of Allergy

A 2007 Cochrane review concluded that there was inconclusive evidence for giving prebiotics to prevent allergic disorders in infants. In a recently conducted RCT a reduced incidence of atopic disease was noted. Infants were fed a partially hydrolyzed formula with either an added mixture of FOS and GOS or maltodextrin placebo in the first 6 months of life. Confirmatory studies of the benefits of prebiotics are needed before any recommendations can be made for the use of prebiotics in infants and toddlers to prevent infection or atopic disease.

Other Disorders

It has been shown that the addition of dietary fiber has ameliorated diarrheal stools when added to infant formula. There have been controlled animal research studies that have shown that prebiotics may prevent or lessen carcinogenic processes, but there have been no RCTs in humans.

Combined Prebiotics and Probiotics to Prevent Allergy

Clinical benefit in preventing allergic diseases by co-therapy with probiotics and prebiotics in pregnant women and their infants was demonstrated in an RCT in Finland. Probiotic/prebiotic treatment showed no effect on the cumulative occurrence of allergic diseases but tended to reduce immunoglobulin E-associated (atopic) diseases. Probiotic and prebiotic treatment reduced the occurrence of eczema and atopic eczema but confirmatory studies are necessary prior to recommendations for their use.

PREBIOTICS AND PROBIOTICS IN INFANT FORMULA

Prebiotics

The European Commission's Scientific Committee on food concluded that they had no major concerns regarding the addition of oligosaccharides to infant formulas, including follow-up infant formulas (formulas modified especially for 6 to 12-month-old infants), up to a total concentration of 0.8 g/dl in ready-to feed formula products. A large multicenter trial to evaluate the safety of FOS supplemented infant formula demonstrated that infant growth was maintained during the 12-week study period for the FOS supplemented infant-formula group without any adverse effects. However, more information, including data from RCTs, is needed before the efficacy of adding prebiotics to infant formulas can be determined.

Probiotics

The overall health benefit efficacy of adding probiotics to infant formula remains to be demonstrated in large RCTs.

SAFETY OF PROBIOTICS AND PREBIOTICS IN INFANTS AND CHILDREN

Most of the probiotics in the market are nonpathogenic assigned generally regarded as safe (GRAS)—US standards or qualified presumption of safety (QPS)—EU standards. Extensive clinical trial literature is available with very few reports of significant complications (bacteremia, fungemia, endocarditis, caries) with the use of probiotics. Mild abdominal discomfort and flatulence are the only adverse effects reported regularly in most of the trials.

Theoretically, probiotics may be responsible for 4 types of side-effects in susceptible individuals.

Infections

There are case reports of probiotics being assumed to have caused infection due to accidental contamination of lines with lyophilized powder opened in the ICU in immune incompetent patient or after tooth extraction. However, organisms that are used as probiotics are easily identifiable and antibiotic susceptibility patterns are known. So infections with these organisms are easy to treat.

Transfer of Antibiotic Resistance

The danger of transfer of antibiotic resistance from probiotics to pathogenic organism is field of major concern. *Enterococcus faecium* could carry resistance factors like vancomycin resistance factor and hence organisms with pathogenic potential like *Streptococcus* and *Enterococcus* are not suitable candidates for use due to safety concerns.

Deleterious Metabolic Activities

Lactobacilli have been associated with dental caries. Other possible adverse effects related to deleterious metabolic activities of probiotics could be deconjugation of bile salts, degradation of intestinal mucus, lactic acidosis, toxic effects due to enzymatic activity and generation of biogenic amines.

Excessive Immune Stimulation

The cell wall components of the probiotics, especially bacterial species can induce cytokines and cause fever, arthritis and even induce autoimmunity.

In the *American Journal of Clinical Nutrition*, Boyle et al have identified potential risk factors for probiotic sepsis and created a scoring system for the same.

Major factors: Immunocompromised state

Minor factors: Central venous catheter, impaired intestinal epithelial barrier (intestinal inflammation, concomitant administration of broadspectrum antibiotics to which probiotic is resistant) and valvular heart disease

1 Major Factor or >1 Minor Factor Caution Against Use of Probiotics

In immunocompromised states like in a newborn or in pregnancy period, probiotics have been used extensively without any adverse events. Ingested bacteria only transiently colonize the gut and do not become permanent residents of the host.

DOSING

Probiotic supplement activity is measured in CFU. A daily dose of 5 to 10 billion CFU's is recommended for most conditions. The CFU's in these preparations can vary tremendously between brands. They should be protected from light, refrigerated and not be taken with food and antibiotics (gap of at least 2 hours between the two). Dry powders in bottles which have to be reconstituted should be stored in

Grade Evidence

"A" Strong, positive, well-conducted, controlled studies in the primary literature, not abstract form.

"B" Positive, controlled studies but the presence of some negative studies.

"C" Some positive studies but clearly inadequate amount of work to establish the certainty of "A" or "B".

dark or amber-colored bottles and reconstituted with cool water but the stability (probiotic viability) tends to go down with time. The dose needed for probiotics varies greatly with the strain and product, e.g. *B. infantis* is effective in alleviating the symptoms of IBS at 100 million CFU/day, whereas studies with VSL#3 use sachets with 300 to 450 billion CFU thrice a day for the same. It is not possible to state a general dose that is needed for probiotics; the dosage has to be based on human studies showing health benefit.

Pediatric Inflammatory Bowel Disease

RK Gupta

INTRODUCTION

Inflammatory bowel disease (IBD) is the umbrella term used to describe chronic intestinal diseases including Crohn's disease (CD), ulcerative colitis (UC) and indeterminate colitis (IC).

In a large prospective study from UK and Ireland CD accounted for 60 percent and UC for 29 percent of childhood IBD. Remaining 11 percent accounted for IC, where a clear distinction between CD and UC was not possible.¹ Incidence of IBD, in particular CD has increased over last 10 to 20 years.²

IBD appears to be more common in countries in the northern hemisphere and in industrialized countries. Highest incidence is seen in Scandinavian countries (5.2 to 10 per 100000 children). Though incidence of IBD is considered less in developing countries, some studies suggest incidences almost similar to west. Incidence of IBD in south Asian population residing in western countries appear to be higher than the native population both in children and adults.¹

The most common time of onset of IBD is during pre-adolescent/adolescent era and young adulthood. A bimodal distribution has been shown with an early onset at 10 to 20 years and a smaller peak at 50 to 80 years of age. About 25 to 30 percent of patients present before 20 years of age.²

CD is a transmural inflammatory disease of gut with episodic progression. It can affect every part of the GI tract from the mouth to anus. UC is a nontransmural inflammatory disease with episodic progression that is restricted to colon.³

ETIOLOGY

The etiology of IBD is multifactorial, resulting from complex genetic, environmental, and immunological interactions.

The risk of IBD in family members of an affected person has been reported in the range of 7 to 30 percent; a child whose both parents have IBD has a >35 percent chance of acquiring the disorder. The gene contributing to CD susceptibility within IBD1 susceptibility locus at chromosome 16 is NOD2 or CARD15 gene. This gene has been identified as a cytoplasmic molecule involved in the sensing of unique microbial cell wall components. Despite the strong association with CD, alterations of NOD2/CARD15 gene are neither sufficient nor necessary for the development of CD. Patients with NOD2/CARD15 genotype have demonstrated fibrostenosing disease, usually in the ileum and earlier disease onset. Other genes studied are IBD5 locus on chromosome 5 and DLG5 locus on chromosome 10.⁴

Environmental factors including breastfeeding, smoking, education, occupation, climate and stress, etc. have been implicated in causation of IBD. Cigarette smoking is a risk factor for CD but paradoxically protects for UC. An infectious etiology has been considered and essentially all patients with IBD have high titers against various bacteria and viruses. Measles virus, *E. coli* especially adherent-invasive type and *M. paratuberculosis* have been considered but no association has been proven.¹ An abnormality in intestinal immunoregulation may be of primary importance in the pathogenesis of IBD.

In summary, IBD results from an inappropriate innate and acquired immune response to commensal microorganisms in genetically susceptible individuals.³

CLINICAL FEATURES (TABLE 1)

Traditionally diarrhea, abdominal pain and weight loss are considered as classical triad of IBD, but only 25 percent of children present with this triad. Clinical suspicion of IBD is raised in children with persistent (>4 weeks)

or recurrent (>2 episodes in 6 months) symptoms such as abdominal pain, diarrhea, rectal bleeding and weight loss. Other symptoms may be fever, growth retardation, malnutrition, nausea, vomiting, psychiatric symptoms, arthropathy, erythema nodosum, secondary amenorrhea, retardation of pubertal development or perianal disease. Growth failure is present at diagnosis in 10 to 40 percent of affected children.²

At the time of presentation about 45 percent children with UC have rectosigmoid disease, 40 percent have left sided disease and 15 percent have pancolitis. In children with CD, 50 to 70 percent present with terminal ileum involvement with more than half also involving colon specially ascending colon. Ten to twenty percent children of CD have isolated colonic disease and 10 to 15 percent has diffuse small bowel disease.⁵

UC commonly present with diarrhea, rectal bleeding and pain abdomen while CD presents as pain abdomen and weight loss which may lead to delay in diagnosis. A mass in the right lower quadrant may be indicative of CD. A rectal examination is important to check for fecal blood, to evaluate for fissures or hemorrhoids and to evaluate fistulas or other perianal disease.⁵

Extraintestinal manifestations are common and are found in about 25 to 35 percent children. These may precede the onset of GI symptoms by months and even years. Common extraintestinal manifestations are:³

- *Musculoskeletal*: Peripheral arthritis, axial arthropathies
- *Dermatological*: Pyoderma gangrenosum, erythema nodosum
- *Ocular*: Uveitis, episcleritis

- *Hepatobiliary*: Primary sclerosing cholangitis, hepatitis
- *General*: Fever, weight loss, malaise
- *Other*: Pancreatitis, nephrolithiasis, amyloidosis
- *Associated autoimmune diseases*: Addison's disease, hemolytic anemia, thyroiditis, etc.

To diagnose growth failure, height and weight must be recorded at diagnosis and all subsequent visits.

MONTREAL CLASSIFICATION OF IBD³

Ulcerative Colitis

E1-proctitis, E2-left colitis, E3-pancolitis

Crohn's Disease

Age at onset: A1-<16 years, A2-17 to 40 years, A3->40 years.

Area involved: L1-terminal ileum, L2-colon, L3-ileocolon, L4-upper GIT, L4+-lower GIT and distal disease.

Depth involved: B1-nonpenetrating, without stricture formation, B2-with stricture formation, B3-internally penetrating, B3p-perianally penetrating.

In 2010, few modifications have been done (Paris modifications) in montreal classification for convenience in pediatric IBD and to denote presence or absence of growth failure.⁶

DIFFERENTIAL DIAGNOSIS

Differential diagnosis for IBD includes common causes of pain abdomen like amebiasis, tuberculosis of gut, constipation, peptic ulcer disease, gastroesophageal reflux disease, urinary tract infection, mesenteric adenitis, etc. Rectal bleeding can be seen in infective colitis, polypoidosis, hemorrhoids, anal fissures, Meckel's diverticulum and intussusceptions. It is important to remember that whenever symptoms of diarrhea, rectal bleeding and pain abdomen occur with weight loss, anorexia, growth failure or extraintestinal manifestations, the diagnosis of IBD must be considered and ruled out.⁶

DIAGNOSTIC WORK-UP

In a child with suspicion of IBD following laboratory studies are suggested:⁵

- CBC, ESR, CRP, anemia studies
- LFTs, serum protein and A/G ratio
- RFTs-urea, creatinine, electrolytes

Stool studies: microscopic examination, culture, for ova and cyst and for calprotectin. Stool culture is must to rule out infectious causes of enteritis or colitis especially *C. difficile*, *Salmonella*, *Shigella*, *E. coli* (O157:H7) and *Campylobacter*. *Giardia lamblia* and *E. histolytica* should also be ruled out by good microscopic examination.²

Table 1: Differences in clinical features of UC and CD³

	UC	CD
Hematochezia	Common	Rare
Diarrhea and mucus	Common	Rare
Small bowel involvement	Rare	Common
Upper GI involvement	Rare	Common
Abdominal mass	Not present	Sometimes
Growth failure	Uncommon	Common
Perianal disease	Rare	Common
Rectal involvement	Universal	Rare
Colonic disease	100%	50–60%
Small bowel ileus	Rare	Common
Colonic obstruction	Rare	Sometimes
Strictures	Rare	Common
Perianal fistulae	Rare	Common
Risk for cancers	Greatly increased	Increased
p-ANCA positive	Common	Rare
ASCA positive	Rare	Common

Fecal calprotectin is a major protein found in the cytosol of inflammatory cells. This protein is stable in stool samples for few days in room temperature and a sample of about 5 g is sufficient to measure its level. It has been suggested by many researchers as a screening test of IBD as well as a test to denote mucosal healing.⁷

Serum ASCA and P-ANCA-ASCA antibodies against *Saccharomyces cerevisiae* and p-ANCA antibodies against the cytoplasm of neutrophils are found in serum of CD and UC patients respectively. P-ANCA is found in about 70 percent of UC while ASCA is found in about 55 percent patients with CD. If IgG and IgA ASCA are both detected, this is 100 percent sensitive for CD. High ASCA titers are associated with onset at young age and with fibrostenosing disease.⁸ When both ASCA and p-ANCA are considered together, they have a specificity of 95 percent and positive predictive value of 96 percent for IBD.⁵

Antibody to *Escherichia coli* outer membrane protein (anti-OmpC), anti-flagellin (anti-CBir-1) antibodies.

Celiac serology: As clinical features overlap, celiac serology should be done.

Imaging

X-ray abdomen plain—if sick child to look for complications as obstruction, toxic mega-colon or perforation.

USG Abdomen—Useful Noninvasive Test

Barium meal with follow through can identify mucosal lesions, strictures, fistulas. It is very important when upper GI endoscopy and colonoscopy are normal in a suspected case.

Barium enema can identify strictures and abnormal mucosa. It is useful to evaluate colon and distal ileum.

CT scan abdomen can identify intestinal abnormality and extraluminal abnormalities as abscess. UC is

associated with mural thickening <1.5 cm, no thickening of small bowel, increased perirectal and presacral fat and target appearance of rectum. Findings consistent with CD include mural thickening >2 cm, small bowel involvement, perianal disease, abscesses and fistulas.

- MRI abdomen and MR enteroclysis has great value nowadays.
- Bone density studies to evaluate bone mineralization.

ENDOSCOPIC EVALUATION (TABLE 2)

Upper GI endoscopy and biopsy- looks at esophagus, stomach and duodenum and is advocated in all cases.

Colonoscopy and biopsy: Colonoscopy including intubation of the terminal ileum and multiple biopsies for histology obtained from all segments of lower intestinal tract is essential. It is the most important investigation to differentiate between CD and UC and identifies localization and extent of inflammatory disease. Intubation of terminal ileum with terminal ileum biopsies should always be attempted as isolated ileal disease may occur in 9 percent of CD cases. Rectosigmoidoscopy alone is insufficient. Upper endoscopy is advocated in all cases irrespective of presence or absence of upper GI symptoms.

Capsule endoscopy is increasing being used in detection of obscure small bowel lesions. It is indicated when CD is strongly suspected but cannot be documented by barium study and upper GI endoscopy. The drawback is high cost and risk of capsule impaction in strictured area of small bowel.

MANAGEMENT

The main goal of medical management of IBD is to achieve clinical and histological remission by suppression of inflammation with the least amount of side effects. Good control of the inflammatory process will decrease chances

Table 2: Endoscopic and histological findings in CD and UC²

	CD	UC
Endoscopy	Ulcers (aphthous, linear, stellate) Cobblestoning Skip lesions Strictures Fistulas Abnormalities in oral or perianal area Segmental distribution	Ulcers Erythema Loss of vascular pattern Friability Spontaneous bleeding Pseudopolyps Continuous distribution with variable proximal extension from rectum
Histopathology	Submucosal or transmural involvement Ulcers, crypt formation Crypt abscess Granulomas (noncaseating, nonmucin) Focal changes Patchy distribution	Mucosal involvement Crypt distortion Goblet cell depletion Crypt abscess Mucin granulomas (rare) Continuous distribution

of surgical intervention. In addition successful treatment should provide adequate nutritional support to promote normal growth and should attempt to minimize alteration in the physical and social functioning of the child.⁵

ASSESSMENT OF SEVERITY (ECCO CONSENSUS)³

Ulcerative Colitis

- *Mild (S1)*: Up to 4 stools per day, normal ESR, pulse rate, Hb, temperature.
- *Moderate (S2)*: Four to six stools per day with no evidence of systemic involvement
- *Severe (S3)*: >6 bloody stools per day, ESR >30, Hb <10.5, HR >90/min, fever
- *Remission (S0)*: <3 stools per day without blood.

CROHN'S DISEASE

- *Mild*: patient is able to walk, can tolerate oral nutrition, no ileus, no abdominal mass, no systemic involvement. CRP may be elevated.
- *Moderate*: weight loss >10 percent, intermittent vomiting, painful abdominal mass but no ileus, lack of response to drug therapy in mild CD.
- *Severe*: cachectic patient or has ileus, an abscess, or persistent symptoms despite intensive treatment.

MEDICAL MANAGEMENT (TABLE 3)

Following drugs may be used in management of IBD:

- *Aminosalicylates*: Mesalamine, Sulfasalazine, Olsalazine
- *Corticosteroids*: Prednisolone, Budesonide, methylprednisolone
- *Immunomodulators*: Azathioprine, 6-Mercaptopurine (6-MP), Methotrexate (MTX), Cyclosporine, Tacrolimus

Table 3: Medical management of IBD

	CD	UC
Mild	Aminosalicylates Antibiotics	Aminosalicylates
Moderate	Corticosteroids Aminosalicylates or AZA or 6-MP or Methotrexate	Corticosteroids Aminosalicylates or AZA or 6-MP or Methotrexate
Severe	Corticosteroids AZA or 6-MP or Methotrexate or Infliximab	Corticosteroids AZA or 6-MP or Methotrexate or Cyclosporine
All cases	Nutritional support Monitor growth closely	Nutritional support Monitor growth closely

- *Biologic agents*: Infliximab Adalimumab
- *Others*: antibiotics and probiotics.

Mild-to-moderate CD is treated initially with 5-aminosalicylic agents or antibiotic therapy with metronidazole and ciprofloxacin. For moderate to severe CD corticosteroids are effective in inducing remission. In patients who have achieved remission with steroids, immunomodulators like azathioprine and 6-MP are helpful in maintaining remission. Steroids are not used for maintenance therapy. Methotrexate may be used for induction of remission in patients who do not respond to steroids for remission. Infliximab, a monoclonal antibody directed against tumor necrosis factor-alpha is being used more commonly to treat moderate to severe CD in patients who do not respond to steroids and immunomodulators. It can be used as first line therapy in CD with severe, perianal, fistulising disease. About 30 percent children may not respond to infliximab. Adalimumab is another biological agent which may be used in severe CD.

In mild-to-moderate UC, 5-aminosalicylic agents are used. In UC topical treatment with enemas is also very effective. In moderate to severe disease steroids are used to induce remission. In severe UC who fail to respond to steroids, cyclosporine is an option. Azathioprine, 5-MP, MTX may be used in refractory cases of UC for maintenance of remission. Biological agents are usually not needed in UC.

Aggressive nutritional support can improve growth parameters in IBD children.⁹ All children with IBD need appropriate nutritional assessment and support to minimize growth retardation due to malnutrition. Special attention should be paid to calorie intake and vitamin and mineral supplementation. Calcium and vitamin D are needed to prevent bone disease.

SURGICAL MANAGEMENT

Surgical management of IBD is typically required for complications of the disease. Indications include perforation/abscess, obstruction, strictures, fistula, toxic mega-colon and malignancy.^{3,6} Ultimately more than 50 percent of patients of CD may require resection. In severe nonresponding UC total proctocolectomy may be needed.¹⁰

INDETERMINATE COLITIS

The term "indeterminate colitis" has been used to delineate a group of patients with IBD limited to colon the diagnosis of CD or UC is not certain. Diagnosis of IC may be kept if in a child with colitis, rectum is normal endoscopically or histologically, or mild ileitis is present. IC is the diagnosis in a child with pancolitis along with anal tags or fissures.¹¹

Nonalcoholic Fatty Liver Disease in Children

Prashant Mathur, Narendra K Arora

INTRODUCTION

Globally overweight and obesity have emerged as an epidemic in children and adults with a spectrum of psychosocial and medical consequences manifesting across the lifespan.¹ Adiposity affects almost all organs of body, but some systems like cardiovascular and endocrine are affected to a greater extent than others. Obese children are at higher risk for hypertension, hyperlipidemia, arteriosclerosis, and diabetes mellitus type-2. Chronic liver disease associated with obesity has been identified in adults as a distinct identity since 1970's, and after almost a decade the condition was reported in children and adolescents. Moran et al provided the first report on severe hepatitis and fibrosis associated with obesity in 3 children aged 10 to 13 years.²

Nonalcoholic fatty liver disease (NAFLD) describes a spectrum of liver disease in persons who have not consumed alcohol in significant amounts so as to cause liver damage, and in whom no other etiology for fatty liver is present. The pathological spectrum ranges from simple hepatic steatosis, to infiltration by inflammatory cells and mild to moderate fibrosis (Nonalcoholic steatohepatitis) leading to cirrhosis.³ With advancing fibrosis, the steatotic component diminishes so that in cirrhotic livers the fat may no longer be seen. Pathologically, NAFLD is a result of complex hepatocellular metabolic dysfunction in which insulin action is deranged, leading to deranged metabolism of fat and free fatty acids and subsequent oxidant mediated damage to the hepatocytes. Several factors sustain and amplify this cytotoxic mechanism. Usually the abnormality of liver is discovered incidentally while evaluating a child for pain abdomen or some other unrelated ailment. In the absence of significant consumption of alcohol in childhood, the nomenclature may not deem fit, as it describes the entity best in adults.

Childhood presents a unique period of growth and development where the causes of fatty liver are enumerable as compared to adults. Broadly, they can be divided into:

HEPATIC CAUSES

- Overweight and obesity related
- Metabolic liver diseases (Wilson disease, galactosemia, hereditary fructose intolerance, glycogen storage disorders, sialidosis, mannosidosis, fucosidosis, hereditary tyrosinemia, alpha anti-trypsin deficiency, homocystinuria, abetalipoproteinemia, wolman disease, tangiers disease)
- Syndromes (Schwachman-Diamond syndrome, Bardet-Biedel syndrome, Alstrom syndrome, Lipodystrophy syndromes, Turners syndrome, Cohen syndrome, Prader-Willi syndrome, Kabuki-Niikawa-Kuroki syndrome, Dorfman-Chanarin syndrome, Poly Cystic Ovarian syndrome)
- Chronic viral hepatitis C (HCV)
- Autoimmune hepatitis, sclerosing cholangitis and others.

Nonhepatic Causes

- Nutritional: prolonged protein calorie malnutrition, total parenteral nutrition, starvation, intestinal bypass surgery, rapid weight loss
- Infections: HIV
- Drugs (glucocorticoids, hypervitaminosis-A, methotrexate, L-asparaginase, zidovudine, amiodarone, didanosine, diltiazem), and toxins (mushrooms - Amanita phalloides)
- Diabetes mellitus
- Inflammatory bowel disease, cystic fibrosis, celiac disease, nephritic syndrome and others.

Thus, one has to consider and rule out several conditions associated with a fatty liver in children before labeling a patient as nonalcoholic fatty liver disease (NAFLD).

This article describes idiopathic childhood obesity/metabolic syndrome associated liver involvement.

PREVALENCE OF NAFLD IN CHILDREN

The exact prevalence of NASH/NAFLD is not well established. Based on the biopsies of potential donors for transplant, autopsy studies of accident victims and hospital based studies, about 2 to 3 percent of lean and 15 to 20 percent of obese adult individuals have steatohepatitis.⁴ Among children the information on its prevalence is scanty. Pooling data from studies performed mainly in tertiary medical centers, the prevalence of NAFLD in obese children has been reported to range from 20 to 77 percent.⁴

Worldwide studies conducted amongst overweight and obese children and adolescents have shown liver involvement in a significant proportion using various diagnostic modalities in isolation or combination. In Canadian children (n=36; 4-16 years) from multiethnic origin with body weight ranged from 114 to 192 percent of ideal weight-for-height, liver biopsy (done in 24 children) had features of some fibrosis in 71 percent and cirrhosis in one. About 30 percent of the cohort had acanthosis nigricans, a known association with insulin resistance.⁵

DIAGNOSIS OF NAFLD IN CHILDHOOD

A pediatrician is likely to encounter NAFLD in three settings:

1. As an incidental finding of raised aminotransferases (more than 2 times the upper normal value of the laboratory) while testing for some other condition in the absence of overt liver disease.
2. During the work-up of an obese child for management.
3. On investigating a child for liver disease.

NAFLD often coexists with other obesity comorbidities and therefore the pediatrician should also be on the lookout for other common *red flags* which may include acanthosis nigricans (insulin resistance), xanthelasma (hyperlipidemias), biliary colic (gall stones), obstructive sleep apnea symptoms, and elevated blood pressure (left ventricular hypertrophy). This association between NASH and components of the metabolic syndrome (MS) has been investigated in children by the United States national institutes of health (NIH) funded NASH Clinical Research Network (NASH-CRN) that found the risk of concurrent MS, as compared to histologic severity of NAFLD, was the greatest in those with severe steatosis (grade 3 as compared to grade 1).⁶ The investigations in a child suspected of NAFLD are guided by two areas of interest.

1. To assess extent and severity of liver involvement: This involves using imaging techniques (ultrasound,

Table 1: Scheme for investigating a child with suspected NAFLD

Initial Laboratory Work-up

Metabolic evaluation

- Fasting lipid profile
- Fasting glucose
- Fasting insulin
- Hemoglobin A1C
- Thyroid stimulating hormone

Chronic Hepatitis Screening Laboratories

- Autoantibody profile
- Alpha 1 antitrypsin phenotype and level
- Serum ceruloplasmin
- Serum iron, total iron binding capacity, ferritin
- Hepatitis C antibody
- Hepatitis B_sAg and Hepatitis B_sAb
- Prothrombin Time

magnetic resonance imaging), studying liver histology for histopathological changes of NASH and its progression.

2. Assessment of comorbidities which determine the setting of its occurrence and outcome. The suggested scheme is as given in Table 1.

ASSESSMENT OF LIVER INVOLVEMENT IN NAFLD

Investigators have used various methods (either singly or in combination) to determine NAFLD in childhood. The presence, degree and pattern of aminotransferase elevation are nonspecific and do not provide etiological differentiation when used in isolation. Ultrasound of the liver has been found to be a good screening tool for assessment of the degree of fat in the liver, but it does not correlate well with the degree of fibrosis. Joseph et al⁷ reported a sensitivity of 89 percent and specificity of 93 percent in detecting steatosis in the liver, and a sensitivity of 77 percent and specificity of 89 percent in detecting increased fibrosis in the liver. The sensitivity of CT scans varied from 54 to 93 percent and specificity between 87 and 97 percent depending on the protocol which was followed.⁸ Ultrasound screening for presence of fatty liver in high risk individuals seems to be a reasonable tool, while CT scans and MRI are very costly and not feasible at the moment for use in routine work-up of suspected NAFLD. Liver biopsy remains the gold standard for diagnosis of steatosis and various degrees of fibrosis, and for comparison of various other diagnostic modalities.

ELEVATED SERUM AMINOTRANSFERASES

Studies have estimated alanine aminotransferases (ALT) and aspartate aminotransferases (AST), either in isolation or in combination to estimate the prevalence of fatty liver in childhood. In NAFLD the ALT and AST levels are elevated to up to 5 times the upper limit of normal. The ratio of ALT:AST in obese individuals is reported to be greater than 1.

The largest community based pediatric data on NAFLD from US was provided by Strauss et al⁹ in 2000, where they estimated obesity and overweight in 2450 children aged 12 to 18 years of age who were surveyed during the NHANES III (1988-1994), and estimated serum aminotransferases in 86 percent of the sample. The overall prevalence of overweight and obese children was 16 percent (BMI between 85th and 95th percentile) and 10 percent (> 95th percentile) respectively. Serum ALT was raised above 30 IU/L in 75 children, and of these 61 percent were obese. The prevalence of raised ALT levels was significantly higher in overweight (5%) and obese children (9.5%) respectively, as compared to normal weight children (1.5%). The odds of raised ALT levels in overweight and obese children as compared to normal weight children was 3.4 (95% CI 1.7-6.8) and 6.7 (95% CI 3.5-12.8). In this study GGTP levels were also significantly raised in overweight (1.3%) and obese (3.9%) children.

FATTY LIVER ON IMAGING

Ultrasonography, CT and MRI scanning are reliable for detecting moderate to severe fatty changes in the liver. Hepatic fat gives hyperechogenic feature on ultrasound compared to spleen, while it gives hypodense shadows on CT scan. Sonologically accurate diagnosis can be made when there is moderate or severe (>33%) fatty infiltration of liver and radiological modalities may not be able to detect or characterize NASH and differentiate it from steatosis alone.¹⁰ MRI is the only noninvasive modality with ability to quantify the fat content of liver.

No imaging method is able to distinguish between simple steatosis and NASH and/or indicate the stage of fibrosis. Though fibrosis and inflammation may result in a typical ultrasonographic pattern, this finding does not reliably distinguish fat from fibrosis or reliably diagnose cirrhosis. Hepatic inflammation, fibrosis and cirrhosis are most accurately diagnosed by liver biopsy results. Routine CT scanning does not add more information on fatty liver disease that what is known from ultrasonography.

Studies have shown that ultrasonography has a low sensitivity (80% and 88.6%) in measuring the degree of steatosis in the liver and that this is confirmed by its inability to discriminate hepatic fibrosis from steatosis. In the largest epidemiological study on fatty liver in obese children using USG, Tominaga et al¹¹ found the prevalence of

fatty liver in 2.6 percent amongst 810 children aged 4 to 12 years old attending a public kindergarten and elementary school in Northern Japan. The study found a direct relationship between the degree of obesity and the prevalence of fatty liver, subcutaneous fat estimation by USG as a better predictor of fatty liver than Rohrer's index, BMI and JSI.

LIVER HISTOLOGICAL EVIDENCE OF NAFLD

No single microscopic finding is diagnostic of NASH. At present liver histopathology is the gold standard for NAFLD clinic-pathologic correlation and exclusion of other causes. In adults, histological features of NAFLD have been well-described and include microvesicular steatosis, perisinusoidal, or pericellular fibrosis, foci of lobular inflammation, lipid granulomas, Mallory hyaline and megamitochondria.¹² The entire histopathological spectrum of NAFLD has been described in children as well. Thus, NAFLD in childhood can present as steatosis, steatohepatitis, fibrosis, and cirrhosis. The major pitfall in the available literature is the smaller sample size and/or non uniform reporting of histopathology reports.

MANAGEMENT OF NAFLD

At present there is no consensus for the treatment of NASH, especially in childhood. Additionally there is no approved pharmacological therapy for childhood NAFLD. But effort needs to be made to prevent development and progression of fibrosis. As the pathogenesis is unclear, management has been largely empirical. Drugs have been targeted at the NAFLD associated conditions like obesity, insulin resistance and diabetes, hyperlipidemia. Prognosis of NAFLD is dependent on the histologic severity and associated risk factors.

The key principles of NASH management are weight reduction and hepatocyte protection. Studies have shown normalization of serum aminotransferases and steatosis with weight reduction. For adults, a 5 to 10 percent weight loss is thought to be adequate for noticeable improvement, but similar figure for children is not known. Dietary modification, changes in lifestyle with increasing physical activity are the key for this effort. Family based interventions are most effective for its sustenance in long run. Ursodeoxycholic acid used are N-acetylcystine, Betaine have also been used with some positive outcomes. Metformin, has been shown to reverse fatty liver in obese adults, adolescents with type-2 diabetes mellitus.¹³

A strong association exists between the presence of steatosis in a donor liver and poor graft function, and as a result cadaveric donor livers with macrovesicular steatosis >40 percent are not used routinely.¹³ Transplantation in the patients of NASH may be complicated by associated comorbidities like obesity, diabetes and hyperlipidemia.

At present transplantation for overt NASH is rare, but it is possible that its contribution may have been underestimated in past and will most likely rise in view of the increasing obesity prevalence. After development of cirrhosis from NASH, the histological features of steatosis and various necroinflammatory changes may become less evident or disappear.

OUTCOME OF NAFLD

There is lack of information on the natural history of the disease in children and most knowledge is extrapolated from adult data. The long term studies indicate that cardiovascular diseases, cancer and liver diseases related mortality are the major outcomes of NAFLD progression. Simple steatosis is considered as a benign condition with little evidence of progression to more severe liver disease, while those with features of steatohepatitis or more advanced fibrosis have the worst prognosis. Children with NAFLD may be at increased risk for cirrhosis if obesity is not reversed and other factors, such as alcohol consumption are not avoided. Weight loss will reverse elevations in aminotransferases and reduce hepatic steatosis, and it may decrease fibrosis. When liver biopsies were performed in adults after weight loss, all had reduced steatosis, but only 50 percent had a reduction in fibrosis. Rapid weight loss may actually increase fibrosis because of an increase of free fatty acids to the liver and increased lipid peroxidation with resultant increased oxidative stress. This led to the conclusion that rapid weight loss should be avoided in these patients. Patients with NASH who develop cirrhosis may require liver transplantation. But, several case reports have shown recurrence of steatosis, steatohepatitis and cirrhosis in post-transplant patients.¹⁴

The progression and natural history of NAFLD has been shown to vary according to the histological type. Identification of cirrhosis in obese children suggests progression of NAFLD to cirrhosis. Probably it also depends on the associated body fat related comorbidities.

Childhood Obesity

Archana D Arya

DEFINITION

Childhood obesity is a complex problem of global concern having assumed epidemic proportions in developed countries. In particular a significant increase has also been observed in India, a developing nation where obesity is primarily restricted to the affluent urban society, whereas in the developed countries it is rampant amongst the lower socioeconomic population as well.

EXCESS OF BODY FAT

The term Overweight denotes excess of fat or other tissues. Ideally, the diagnosis of obesity should be based on direct demonstration of increased amount of body fat, but this is not practical and requires expensive equipment.

The measures commonly used to define obesity are body weight, weight for height, body mass index, skin fold thickness and waist to hip ratio. Each method has its advantages and disadvantages.

Body Weight

Body weight for age is easy to obtain and hence is frequently used as an index for obesity. This measurement is inadequate since it does not take into account the stature of the child.

Weight for Height

It is a better index for assessing obesity. Weight for height more than the 90th percentile, or body weight more than 120 percent of the ideal body weight (mean weight for height) has been defined as obesity. Body weight more than 130 percent of the ideal body weight is considered as severe obesity. Growth charts have been developed for this purpose.

Body Mass Index

The WHO has recommended using body mass index (BMI) as an index of being overweight or obese. Body mass index is calculated by dividing the weight in kilograms by height in meters squared (kg/m^2).

Normal BMI value for adults is 19-22 kg/m^2 with BMI 25 to 29.9 being termed as overweight and >30 as obese.¹

The adult BMI values cannot be applied to children since the BMI does not remain static in children and changes as they grow. A BMI of 22 kg/m^2 in an 8-year-old male child will fall above the 97th percentile for his age (obese) whereas it would be normal for an adult.

Hence, it is important to use age related standards in children. Age and sex related percentile charts are available for BMI for boys and girls from CDC (USA), KN Agarwal et al and recently from Khadiolkar et al.² The CDC charts are depicted in Figures 1 and 2.

Obesity is defined as BMI >95 th percentile for age and sex.

Body mass index (BMI) between 85th to 95th percentile for age and sex is considered as overweight or at risk for obesity.

Body mass index (BMI) is the most practical method for assessing obesity in a clinical practice and correlates well with the risk of obesity related medical complications.

Skin-fold Thickness

Measurement of skin fold thickness from the trunk and extremities provides a reliable estimate of obesity and regional fat distribution. The correlation of multiple skin folder thickness (SFT) measurements with total body adiposity is 0.7 to 0.8. An experienced person should do the measurements. This method is useful for community pediatrics or large studies but is not used often for routine assessment of obesity. Skin fold thickness centiles for Indian children are available for reference.³

There is limited data from our country but an increase in the prevalence of obesity has been observed in the urban areas and in children of obese parents. A study of 4700 school children aged 13 to 18 years in an urban area of Chennai revealed that the prevalence of overweight children based on the BMI was 17.8 percent for boys and 15.8 percent for girls.⁹

Kapil et al from Delhi have reported a prevalence of 16.2 percent in 2002 while Misra et al reported a prevalence of 29 percent from Delhi in 2008¹⁰⁻¹³ reflecting a marked increase in prevalence of overweight and obesity in urban children in Delhi.^{13,14}

Khadilkar et al in a multicentric study (2009) from 5 geographical zones of India, have reported that compared to Indian data recorded in 1989, the 97th percentile for boys and girls weight at 18 and 17 years respectively was 14.7 kg and 8 kg higher.¹⁵

PATHOPHYSIOLOGY

Increase in the adipose mass is a result of increased storage of triglycerides, the primary stored fuel in humans. This energy surplus occurs when more calories are ingested as food than are expended. Therefore obesity results from either excess consumption of calories or lack of activity, or both.

In normal circumstances the amount of body fat is regulated by a control of appetite and satiety by the hypothalamus. Recent research has identified the feedback hormone, Leptin, which is secreted from the adipose tissue and has a role in the hypothalamic control of appetite. The *ob* gene responsible for the secretion of Leptin has also been identified. Further research in this area will give us a better idea of the mechanisms of obesity and may result in useful new therapies.

ETIOLOGY

The clinical evolution of obesity in children is often multifactorial. The most common cause of obesity in childhood is environmentally determined (simple obesity) with no demonstrable disease. Genetic factors also play a major role followed by endocrine disorders, central nervous system (CNS) and chromosomal disorders, psychosocial factors and drugs. The causes are listed in Table 1.

Genetic Factors

Several monogenic obesity syndromes have been identified. The known genes involved include leptin, the leptin receptor proopiomelanocortin (POMC), prohormone convertase 1, melanocortin receptors 3 and 4, and the transcription factor single-minded.¹

MC4R mutations are the most frequent known cause of monogenic human obesity, occurring in up to 4 percent of early-onset and severe childhood obesity.¹⁶

It is highly probable that childhood obesity is polygenic with susceptibility conferred via complex genetic factors. It is estimated that 30 to 50 percent of the tendency toward excess adiposity can be explained by genetic variations.¹⁷

It has also been demonstrated that the BMI of adopted children correlated more closely to their biologic parents than the adoptive parents¹⁸. Furthermore BMI of identical

twins appears to be similar whether they are reared together or apart confirming the role of genetic factors in obesity.

Environmental Factors

Environmental factors that influence eating behaviors and physical activity influence the development of obesity. Today's children live in an obesogenic food environment that readily provides calorie dense foods. They are consuming diets that are too high in fats and sugar and very few helpings of fruits, vegetables, grains and dairy.

Failure to lose weight despite low caloric intake is often due to misreporting of food intake and physical activity.

Physical activity in children has declined over the last few years and the life style has become sedentary. Indoor entertainment such as television viewing, computers, etc. have become very popular. Relationship between television viewing and obesity may be due to increased food consumption during viewing, influence of food advertisements on eating patterns and decreased energy expenditure. It has recently been shown that television viewing may contribute to obesity by lowering the basal metabolic rate in obese as well as lean individuals. Academic pressure contributes further to the sedentary lifestyle.

Pathological Factors

Organic pathological causes may underlie obesity in a smaller number of children. However, these are important because these are diagnosable and treatable conditions. The physician and parents are also looking for a cause other than simple obesity and may not be satisfied unless endocrine and other causes are ruled out. Pathological causes of obesity are listed in Table 1.

If the child is above average in stature and has overweight family members, organic pathology is unlikely. If the child is below average in stature, especially with slow growth, pathologic cause must be ruled out. Since, appetite and satiety are controlled by the hypothalamus, tumors, malformations and damage to this region can cause obesity. Dysmorphic features should arouse the suspicion of genetic syndromes associated with obesity (Table 1).

CLINICAL MANIFESTATIONS

Children with simple obesity are usually tall for their age and may have slightly advanced bone ages. Puberty starts a little earlier than the lean peers. Psychological disturbances may be present, but it is sometimes difficult to determine if they are the cause or result of obesity.

Endocrine causes of obesity usually result in short stature. In hypothyroidism obesity is due to decreased energy expenditure. Gross obesity is seldom due to hypothyroidism. Bone age is usually delayed in these children. Weight loss may occur once treatment is started but is due to decrease in fat-free mass.

Table 1: Causes of obesity

- Genetic
- Simple obesity (environmentally determined)
- Pathologic
 1. Endocrine
 - Hypothyroidism
 - Steroid excess
 - Growth hormone deficiency
 - Pseudohypoparathyroidism
 2. CNS
 - Hypothalamic tumors
 - Malformations
 - CNS damage
 3. Syndromes
 - Prader-Willi
 - Laurence-Moon-Biedl
 - Beckwith-Wiedmann
 - Carpenter
 - Turner
 - Klinefelter
 4. Leptin deficiency
 5. Psychiatric disturbances
 6. Drugs: Corticosteroids, valproate, etc.

Steroid excess may be due to medications, production from a tumor or Cushing's disease, which is characterized by central distribution of fat, striae, decreased growth rate and hypertension. Since, cortisol production and clearance are increased in obesity, 24-hour urine free cortisol is one of the most sensitive tests. Dexamethasone suppression test may be done to differentiate simple obesity from Cushing's disease.

Growth hormone (GH) deficiency may also manifest as obesity that is truncal and is associated with slow growth.

Central nervous system (CNS) disorders lead to sudden rapid weight gain, insatiable appetite and other neurological symptoms.

Children with genetic syndromes usually have dysmorphic features, hypotonia, hypogonadism and other specific associated features.

CONSEQUENCES OF OBESITY

Adult Obesity

Forty percent of overweight children become obese adolescents and 75 to 80 percent obese adolescents become obese adults.¹⁹

Endocrine Consequences

Alterations in endocrine functions are present in obese children and are a result and not cause of obesity, since they normalize with weight loss. These changes have been summarized in Table 2.

Table 2: Effects of obesity on endocrine hormones

Growth hormone	↓ basal levels		
	↓ response to pharmacological stimuli		
IGF1	Normal		
Thyroid hormones	↑ T ₃ level		
	Normal T ₄ and TSH		
Cortisol	Normal S. cortisol level		
	(↑ production and clearance)		
ACTH	Increased		
DHEA	Increased		
Sex steroids	Females		Males
	↑ LH	↑ LH:FSH	N testosterone
	↓ FSH		
			↑ estrogens
Insulin	Increased		
Calcium and Phosphorus	Normal		
Parathormone	Increased		

Acanthosis Nigricans Metabolic Consequences

1. Insulin Resistance: Obesity leads to insulin resistance. A higher amount of insulin is produced to maintain normal glucose levels, leading to hyperinsulinemia and an increase in the insulin:glucose ratio.
2. Acanthosis Nigricans (AN): These are hyperpigmented, velvety folds of skin, usually present behind the neck, and in the axilla and groin. It is a manifestation of high insulin level. Acanthosis nigricans (AN) are associated with both T2DM and insulin resistance (IR), but the strongest correlation is with obesity.²⁰
3. Type 2 Diabetes Mellitus: Insulin resistance (IR) leads to decrease in insulin mediated glucose uptake and may manifest as abnormalities in the glucose tolerance test and Type 2 diabetes mellitus (T2DM), especially in adolescents with a family history of diabetes mellitus.

The greater prevalence of childhood obesity has resulted in greater prevalence of T2DM in children and adolescents.²¹ Type 2 diabetes mellitus (T2DM) now accounts for 20 percent of diabetes in children aged 10 to 19 years.²²
4. Polycystic Ovarian Disease: Insulin regulates the ovarian androgens through LH. Hence in females, hyperinsulinemia may be associated with benign premature adrenarche followed by functional ovarian hyperandrogenism which leads to hirsutism and menstrual irregularities. Some girls may develop high LH levels and cysts in the ovaries.

Although not a co-morbidity per se, an earlier onset of pubarche and thelarche is associated with an elevated BMI.^{23,24} Whether it is also associated with an earlier onset of menarche is controversial, a question that has been extensively reviewed.²⁵

5. Dyslipidemia: Obesity leads to increase elevation of plasma triglycerides and VLDL. Total body cholesterol synthesis may also increase. Lipid abnormalities have been found in 12 to 17 percent of overweight and obese children.²⁶ Weight reduction normalizes levels of triglycerides and cholesterol and increases levels of HDL.
6. Metabolic Syndrome: Is a constellation of cardiovascular risk factors, comprising abdominal obesity and two or more of the following: elevated triglycerides, low HDL cholesterol, high blood pressure, increased plasma glucose.^{27–29} Prevalence among 12 to 19 years olds in the United States is about 4.2 percent.³⁰ The risk of the metabolic syndrome is nearly 50 percent in severely obese (BMI >40.6 kg/m²) adolescents.³¹
7. Hypertension: Systolic blood pressure correlates with BMI, skin fold thickness, and waist-to-hip ratio in children and adolescents. The relative risk for hypertension in obese children (BMI >95th percentile) was 3.26 after three consecutive blood pressure screenings.³²
8. Nonalcoholic Fatty Liver Disease: The prevalence is unclear and depends on the detection method. Ten to twenty-five percent of obese children have elevated transaminases, primarily alanine aminotransferase (ALT) with levels increasing with the degree of obesity. Weight reduction is an effective treatment for nonalcoholic fatty liver disease (NAFLD).³³ Although, a benign clinical course is typical of NAFLD, it may be associated with increasing fibrosis and, rarely, progression to cirrhosis.³⁴

Medical Consequences

These manifest as hypertension heart disease, hypoventilation and hypercapnia (pickwickian syndrome). Obesity can also result in gall stones³⁵ blounts disease, genu valgum and slipped capital femoral epiphysis.³⁶ Obese children are up to six times more likely than lean children to have obstructive sleep apnea.³⁷ Obstructive sleep apnea is independently related to the development of hypertension, cardiovascular diseases, behavioral disorders, poor school performance in children, and poor quality of life in adults.³⁸

Psychosocial Problems

It may become an issue for many over-weight and obese children and adolescents.³⁹

APPROACH TO DIAGNOSIS

Obesity is a symptom rather than a disease and may be a precursor for other diseases. A detailed history must be obtained in every child regarding.

- Rate of weight gain
- Pattern of linear growth
- Milestones
- Appetite and Lifestyle: Record a rough daily dietary intake. Ask about the time spent exercising or outdoors and time

spent watching TV and on other indoor activities such as reading, computer, etc.

- Headaches
- Visual disturbances
- Menstrual disturbances in postmenarchal girls.
- Family history of obesity, thyroid disorders, diabetes mellitus, hypertension and heart disease
- Cultural and social history regarding eating patterns and psychological.

Physical Examination

- Measure the height and weight to determine if the child's height is appropriate for age
- Plot the weight for height and BMI
- Check vital signs including blood pressure
- Look for acanthosis nigricans
- Identify abnormalities of the hands, feet and other syndrome associated features
- Complete physical examination of the thyroid and other systems should be done
- Assess pubertal status and check for gynecomastia in boys.

In prepubertal obese boys the penis often looks small and is a cause of great worry to parents. This is usually due to the penis being embedded in the suprapubic pad of fat. In such cases a stretched penile length should be measured. The penis should be stretched between the thumb and the forefinger. The suprapubic pad of fat should be depressed with a ruler and the penis should be measured along the dorsum till the tip of the glans penis. The foreskin should not be included in the measurement.

INVESTIGATIONS

Who Should be Evaluated?

All children with a BMI above the 85th percentile should be evaluated. Diagnostic investigations are aimed at identifying the cause and to look for consequences of obesity. These should preferably be done under the guidance of a pediatric endocrinologist. Guidelines for evaluation have been summarized in Table 3.

MANAGEMENT OF OBESITY

Management of obesity is a very tough task for the physician since most pediatric interventions may result in only small changes in weight, and are often associated with relapses in weight gain.

In cases of pathologic obesity, the underlying cause should be treated wherever possible.

Management of simple obesity includes alteration in lifestyle and dietary management. Pharmacological interventions have a limited role in the management of childhood obesity.

Table 3: *Diagnostic evaluation*

Disease suspected	Test
Hypothyroidism	FT4, TSH
Cushing disease	urine free cortisol or Morning and evening S. cortisol
GH deficiency	GH stimulation test, IGF1, IGFBP-3
Genetic syndromes	Karyotyping: Deletion of Chromosome 15
CNS disorder	MRI of the brain
Consequences of obesity	
BMI	
85-94th percentile	Fasting lipid profile, Bone age
> 95th percentile	Fasting lipid profile, blood glucose and insulin HbA _{1c} / Glucose tolerance test with insulin levels, Bone age

ALTERATIONS IN LIFESTYLE

Diet Management

Diet restriction in children has to be done very carefully and under strict supervision since it can affect the growth of the child and cause nutritional deficiencies. The aim should be restriction of calories without affecting the nutrition or growth.

Dietary management will depend on the age and presence/absence of complications.

Less than three years of age: strict calorie restriction is not recommended, but the practice of overfeeding can be avoided.

Three to seven years with no associated co-morbidities: Weight maintenance is required. Try to prevent weight gain rather than advising weight loss so that as they gain height, their BMI reduces gradually.

Three to seven years with co-morbidities: Weight loss is recommended.

>7 years: Weight loss is recommended.

Weight maintenance: Changes in diet should be permanent, rather than short term. Since fast foods soft drinks, etc. are the major culprits, they should be restricted. Restrict calories from saturated fat. Simple changes like taking skimmed milk instead of whole milk, stop applying ghee/butter to chapattis, which is a very common Indian practice, can reduce calories without affecting nutrition. Increase the consumption of whole grain, fruits and vegetables. Intake of fiber rich foods is important since they improve satiety. Restrict eating out and encourage the whole family to eat the same food as the child.

Weight loss should be slow and not rapid. However in older and grossly obese children who have developed complications related to obesity and have achieved their final height, more severe calorie restriction may be undertaken. This can be done as a balanced hypocaloric diet in

which the intake is reduced by 2400-2900 kJ per day. This induces a weight loss of 0.5 kg per week.

Another intensive regime which has been tried is the Protein-sparing modified fast (PSMF). This supplies a daily intake of 2500-3500 kJ and 1.5-2.5 g of high quality protein per kg of ideal body weight. Carbohydrate intake is restricted to 20-40 g daily. Daily intake of vitamins and 1500 ml of water is also recommended. This results in rapid weight loss and should be done under strict medical supervision. It should not be continued for more than 1-3 months. Side effects such as cholelithiasis, hyperuricemia, etc. have been observed. Long-term studies comparing the 2 diets showed similar mean weights. This suggests that the PSMF diet has no long lasting benefit compared with a balanced hypocaloric diet.

EXERCISE

Exercise should be encouraged since sedentary lifestyle has a major contribution to obesity. In the absence of caloric restriction, moderate exercise does not generally cause weight loss. However, in combination with decreased caloric intake, exercise can achieve significant weight loss.

Physical fitness, even without weight loss, may offer some health benefits. Improvement in cardiovascular fitness is associated, in young adults, with improvement in cardiovascular disease risk factors over a 7 years period.⁴⁰

Physical activity should be a part of the daily curriculum in schools. Encourage them to participate in sports that they enjoy such as tennis, football, walking, dancing, swimming, etc. Reduce TV viewing and encourage them to do chores at home too. Studies have shown that supervised resistance training programs are safe for preadolescents. The intensity and duration of a resistance exercise set must be appropriate to the level of maturity of the growing bones and muscles.

BEHAVIOR MODIFICATION

Modification of the child's behavior should be done in conjunction with the diet and exercise management. This should be done as a team with a therapist. Gain insight into the child's problems and the family environment. Educate the family about the importance of healthy foods and exercise and give rewards for achieving goals. Build the child's self-confidence and esteem and help him deal with the peer pressure. Behavior modification helps in achievement of long-term goals.

PHARMACOTHERAPY

Most of the medications used for obesity in adults, have not been used in children frequently or for a prolonged duration and are not recommended routinely because of the high risk of side effects.

The pharmacotherapeutic agents orlistat, and metformin (not FDA approved for the treatment of obesity) are most commonly used at present.

Orlistat specifically inhibits intestinal lipase and can reduce fat and cholesterol absorption by approximately 30 percent.⁴³ It is approved by FDA for use in children >12 yr of age. Studies showed that use of orlistat was associated with a significant fall in BMI of 0.7 kg/m², but treatment was associated with increased rates of gastrointestinal side effects including abdominal discomfort, pain, and steatorrhea. Side effects are usually mild to moderate and generally decrease in frequency with continued treatment. It prevents the absorption of fat soluble vitamins, hence vitamin supplements must be given during treatment.

There have been reports of serious liver injury including liver failure in patients taking Orlistat between 1999 and 2008. Hence, US FDA is studying the drug for its side effects currently.

Metformin reduces hepatic glucose production and plasma insulin, inhibits lipogenesis, increases peripheral insulin sensitivity, and may reduce appetite by increasing levels of glucagon-like peptide, but its mechanism of action on weight is unresolved, hence it is not used or approved for weight loss.

Sibutramine, a nonselective reuptake inhibitor appetite suppressant that is most potent for serotonin and norepinephrine, but also blocks dopamine reuptake^{41,42} was approved for children >16 years of age by the US FDA for treatment of obesity. It has now been withdrawn from the market because of increased risk of cardiovascular events such as heart attack and stroke.

It has been suggested that overweight children should not be treated with pharmacotherapeutic agents unless significant, severe comorbidities persist despite intensive lifestyle modification. In these children, a strong family history of T2DM or cardiovascular risk factors strengthens the case for pharmacotherapy.⁴⁴

It is also suggested that pharmacotherapy be offered only by clinicians who are experienced in the use of anti-obesity agents and are aware of the potential for adverse reactions.⁴⁴

BARIATRIC SURGERY

Surgery is seldom performed in children unless there is a life threatening complication. Roux-en-Y gastric bypass has been done in older adolescents and adults. It is a last resort for adolescent who have a high risk of mortality due to obesity.

MANAGEMENT OF CONSEQUENCES

Dietary restriction, exercise and lifestyle management manages most of the consequences of obesity. Specific medical treatment may be required in obese children with

Table 4: Guidelines for preventing obesity

Infancy

- Encourage sustained breastfeeding (>3-6 months)
- Discourage early introduction of solid foods (emphasize vegetables)
- Goal: Moderate rates of weight gain, including in low-birth weight infants (throughout childhood). Rapid catch-up growth may be detrimental.

Older children

- Encourage intake of vegetables and fruits
- Minimize intake of juice, cold drinks, chocolates, etc.
- Discourage eating out too often
- Encourage physical activity (outdoors and at home)
- Discourage TV viewing (<1 hour daily)
- Behavioral
- Emphasize family-based meals, avoid cooking special meals for kids
- Do not use food as a reward or punishment
- Provide parental modeling of healthy diet, physical activity, and minimal television viewing
- Offer positive reinforcement for healthy choices, avoid criticism
- Support healthy body image, emphasizing strength and health rather than weight and appearance

complications such as diabetes mellitus, hypertension, grossly abnormal lipid profiles, hirsutism, and menstrual abnormalities.

PREVENTION OF OBESITY

Long term follow up of children treated with diet, exercise and behavior modification has shown significantly lower weights 5 to 10 years later than for children treated in other ways. However not all obese children treated successfully initially were able to maintain their reduced relative body weight.

Children should develop healthy eating habits right from infancy. They should have an exercise pattern that prevents excess weight gain. This is especially important for children in high-risk groups, e.g. those with obese parents or family history of diabetes, heart disease, etc. Health professionals should inform parents of the potential risks and provide instructions on preventive measures at an early age. Guidelines for preventing obesity are summarized in Table 4.

Growth Monitoring and Short Stature

Vaman Khadilkar

INTRODUCTION

Growth monitoring is a screening tool to diagnose nutritional, chronic systemic and endocrine disease at an early stage. Growth monitoring has the potential for significant impact on mortality and morbidity even in the absence of nutrition supplementation or education.¹ Monitoring the growth of a child requires taking the same measurements at regular intervals and seeing how they change. Growth monitoring practices differ greatly among pediatricians and often are not based on evidence. Indian Academy of Pediatrics therefore wrote consensus guidelines for growth monitoring as per IAP Action Plan 2006.²

AIMS AND RATIONALE OF GROWTH MONITORING

Primary aim of growth monitoring is to identify children with growth deviation i.e. under-nutrition and over nutrition and to identify diseases and conditions that manifest through abnormal growth. Secondary aims are to discuss health promotion related to feeding, hygiene, immunization and other aspects of the child's health and behavior; education of parents to allay their anxiety about their child's growth. Growth monitoring also helps to sensitize health care workers to use growth charts in their day to day practice.

GROWTH CHARTS

Although the world's children appear to follow a similar growth pattern, still there are variations due to ethnic, geographical, and regional factors giving different rates of maturation and adult stature. The final height of different ethnic groups is different, even accounting for secular trends. Thus for assessment, an up-to-date national representative sample of population data are ideal as growth standards. The Indian Council for Medical Research (ICMR) undertook a nationwide cross sectional

study during 1956 and 1965 to establish Indian reference charts. The measurements were made on children of the lower socio-economic class and hence cannot be used as a reference standard at the present time. The growth charts compiled by Agarwal et al were based on affluent urban children from all major zones of India measured between 1989 and 1991. The data is now 20 years old and does not reflect the growth of modern Indian children.^{3,4} In 2010-2011 Khadilkar et al have published growth charts on affluent children from 5 to 18 years and have also compared the growth of 2 to 5-year-old affluent Indian children with the new WHO growth charts. Based on these two papers growth charts for affluent Indian children from 2 to 18-year-old are now compiled by the author and are ready for clinical use.^{6,7} These are the most modern national growth references curves available at present in India. WHO published new growth standards for children under the age of 5 years in 2006 which are being adopted in many countries including India as a global single standard of childhood growth for the under five children.

BASICS OF GROWTH CHARTS

Growth chart consists of an x axis which is usually age in years or months and a y axis that changes according to the reference e.g. it can be height in cm or inches, weight in kg or body mass index in kg/m². The x axis is usually divided into 12 equal parts (months) for each year. Standard growth chart has 7 percentile lines and include 3rd, 10th, 25th, 50th, 75th and 97th percentiles. Any individual who is below 3rd and above 97th percentile is considered out of normal range. For the BMI charts however there are 85th and 95th percentile lines which indicate overweight and obesity cut offs. Proportion charts use Z score lines instead of percentile lines and discrepancy of more than 2 Z scores in the upper and lower segment is considered abnormal. On the growth velocity chart 25th

percentile is the cut off line for defining low height velocity. The correlation between Z scores and percentiles can be confusing and in the recent WHO MGRS 2006 study, these correlations have been spelt out by the WHO and are given in the table (Table 1) below for clarity of understanding.

Doctors and health care workers find it difficult to interpret various cut offs for diagnosis of underweight, overweight, stunting, wasting, etc. which have also been clearly spelt out in the new WHO MGRS study and are given below (Table 2). These make it easy for the practicing pediatrician and health care worker to follow as a guideline for management and referral.⁵

IMPORTANCE OF ANTHROPOMETRY OVER TESTS

Anthropometry scores over all the available endocrine tests in the assessment of growth failure. Hence it is of paramount importance that appropriate growth charts are used. Plotting a child's growth must always be the starting point in the investigations of growth failure. Longitudinal data plotted over a period of time is far more useful than a single record of height and weight. Observation of growth pattern usually over a period of minimum one year is necessary before a child is subjected to rigorous endocrine evaluation.

GROWTH STANDARD VS REFERENCE

Growth charts mainly belong to two types: growth standards and growth references. Growth standards are prescriptive and define how a population of children should grow given the optimal nutrition and optimal health. Growth reference on the other hand are descriptive and are prepared from a population which is thought to be growing in the best possible state of nutrition and health in a given community. These describe the growth of children at that time. They represent how children are growing rather than how they should be growing.

WHO 2006 growth charts for children under 5 years is an example of growth standards. They delineate how children of the world under the age of 5 years should grow if most of the controllable variables are kept optimal. (IOTF classification) as opposed to this 1989 K N Agarwal data (3) and 2007 Indian growth charts by Khadilkar et al⁶

Table 2: Growth parameters and their interpretation for the WHO charts

Z-Score (Percentile)	Length/Height for age	Weight for age	BMI for age
>3 (99)	May be abnormal	May be abnormal	Obese
>2 (97)	Normal	(Use BMI)	Overweight
>1 (85)	Normal	Use BMI	Risk of overweight
0 (50)	Normal	Use BMI	Normal
<-1 (15)	Normal	Use BMI	Normal
<-2 (3)	Stunted	Normal	Normal
<-3 (1)	Severely stunted	Underweight	Wasted
		Severely underweight	Severe wasted

for affluent children are an example of growth references which describe how children in India were growing at the given time and are references and not standards.

Advantage of having a growth standard such as WHO 2006 charts is that children of all countries, races, ethnicity can be compared against a single standard thus assessment becomes more objective and easy to compare. The disadvantage of using charts such as these are likely to over diagnose underweight and stunting in a large number of apparently normal children⁷ in the developing countries such as India.

Advantage of a reference is that they are true representative of the existing growth pattern of children and allow us to study the secular trend in terms of height, weight and obesity. The downside of reference curves is that they need to be updated at least once in a decade and in modern times as obesity is on the rise they are likely to define overweight children as normal.

WHO 2006 GROWTH STANDARDS

In 2006 WHO produced growth standards for children under the age of 5 years. The standards are derived from children who were raised in environments that minimized constraints to growth such as poor diets and infection. In addition, their mothers followed healthy practices such as breastfeeding, and not smoking during and after pregnancy. Because the standards depict physiological human growth under optimal environmental conditions, they provide an improved tool for assessing growth. These charts thus are prescriptive standards and not descriptive references.

These standards provide an opportunity to redefine and revitalize actions to promote optimal child growth, foster the adoption of "best practices", such as incorporating height and BMI to assess the dual burden of under and over-nutrition (stunting and overweight); provide coherence between national and international infant feeding guidelines that recommend breastfeeding as the optimal source of nutrition during infancy and the charts are

Table 1: Correlation between percentiles and Z-scores for WHO 2006 charts

Z-Score	Exact percentile	Rounded percentile
0	50	50
-1	15.9	15
-2	2.3	3
-3	0.1	1
1	84.1	85
2	97.7	97
3	99.9	99

recommended for assessing the pattern of infant growth; and harmonize growth assessment systems within and between countries.⁸

WHO recommends using -2Z (3rd percentile) scores for diagnosis of stunting and underweight and -3Z (1st percentile) for the diagnosis of severe stunting and severe underweight.

HOW INDIA AND OTHER COUNTRIES PERFORM ON THESE CHARTS²

In developing countries use of WHO 2006 growth charts will likely over diagnose stunting or underweight or both. In a recent multicentric study done on 1493 affluent pre-school Indian children (selected from all zones of India) published by the author the Mean Z scores for height, weight, body mass index and weight for height [-0.75(1.1), -0.59(1.1), -0.19(1.22) and -0.26(1.18), respectively] were below the WHO 2006 standards. The overall incidence of stunting was 13.6 percent and underweight was 8.5 percent amongst affluent Indian children under the age of five years. This percentage is likely to be higher in rural areas and in under privileged urban areas although at the present time no such data is available from India.

Concerns regarding adoption of new WHO 2006 is also expressed by many authors from many parts of the world such as Indonesia, Czechoslovakia, Malawi, etc. as these standards are likely to over diagnose stunting and underweight. Many authors have expressed caution regarding changing infant feeding policies based on WHO standards for the present time.

NEW 2007 AFFLUENT INDIAN GROWTH CHARTS (FIGS 1 TO 4)

The Need for New Charts

The previously available growth reference curves in India were based on the data collected by Agarwal et al in 1989 which were published in 1992 and 1994 and are almost 2 decades old. WHO recommends that each country should update its growth references every decade and hence new growth references were produced in 2009.

Data Collection

The Indian Academy of Pediatrics divides India into 5 zones i.e. North, South, East, West, and Central. The nutritionally well off areas were identified based on per capita income of cities (from IAP zones). Data collection lasted from June 2007 to January 2008. Of the 19834 children measured, measurements for 18666 were analyzed (10496 boys and 8170 girls) where 5184 (3218 boys, 1966 girls) 3000 (1678 boys, 1322 girls), 698 (696 boys, 1002 girls) 6920 (3837 boys, 3083 girls) and 1864 (1067 boys, 797 girls) children were from the North, South, East, West and Central zones, respectively. The differences between

zones were not significant. Standard percentiles were generated for height, weight and body mass index (BMI) using the universally accepted LMS method, which constructs growth reference percentiles adjusted for skew.⁹

OBSERVATIONS

Secular Trends in Height

The 50th percentile for boy's height was greater than that of the 1989 data at all ages. The 97th percentile at 18 years was 1.7 cm greater than in 1989. The 50th percentile for girls' height was greater than in 1989 at most ages, the greatest difference being 3.1 cm at 12 years. The median final height for girls was similar to 1989, but the 97th percentile was 2.4 cm greater, indicating increased variability.

Alarming Rise in Obesity

The 50th percentile for boys' weight was greater than in 1989 at all ages except 5 years, maximum 6.5 kg at 14 years reducing to 2.9 kg at 18 years. At 18 years the 97th percentile was 14.7 kg, higher than in 1989. The 50th percentile for girls weight was lower than the 1989 up to the age of 6.5 years and higher afterwards, maximum 8.0 kg at 17 years. Unlike in boys, there was no reduction in difference in weight approaching adulthood. Compared with the 1989 data, average difference in the 97th percentile was similar to the 50th percentile (6.8 kg and 4.7 kg, respectively) in girls which was in stark contrast to the data on boys, where the difference was much greater (12.8 kg and 4.1 kg, respectively). In boys, the median BMI values were higher at almost all ages compared with the 1989 data. The difference in the 95th percentile in the two datasets was 2.3 at 18 years. In girls the median BMI values were higher at almost all ages, the maximum difference being 1.1 kg/m² at 18 years.⁶

This dataset was examined for the prevalence of overweight and obesity by international standards. The overall prevalence of overweight and obesity was 18.2 percent by the IOTF classification and 23.9 percent by WHO standards. The prevalence of overweight and obesity was higher in boys than girls. Mean BMI values were significantly higher than those reported in the 1989 data from 5 to 17 years at all ages and for both sexes. The rising trend of BMI in Indian children and adolescents observed in this multicentric study, rings alarm bells in terms of associated adverse health consequences in adulthood.¹⁰

COMPARISON OF 2007 AFFLUENT INDIAN CHARTS WITH CDC AND UK CHARTS

On comparison with the US (NCHS 2000) and UK (1990) data, the height percentiles for both boys and girls are similar until the age of puberty but thereafter Indian affluent children remain shorter and do not show the pronounced pubertal spurt. This is seen in both sexes and

may be related to genetic difference in the populations. On the BMI charts the 75th percentile for the current data was very close to the US and UK 85th percentile on BMI charts, especially after 7 years in boys and 9 years in girls. Boys on the 75th percentile in our study had a mean BMI of 24.2 and girls had a mean BMI of 24 at 18 years, this value is just under the adult cut-off (25) for overweight.¹¹ Seventy-fifth percentile values on the current BMI curves may therefore be used as a cutoff for screening for overweight boys and girls.

BMI CHARTS

As obesity in childhood is increasing around the world, using descriptive growth charts for weight may under diagnose obesity in children as these charts tend to “normalize” obese children as the whole population from where the data is collected is on the higher side of the weight scale. It is therefore suggested that we use prescriptive growth standards for BMI in children. Such charts are made available by WHO. These charts tend to construct percentiles in such a way that they meet the adult cut off for overweight and obese at 25 and 30 BMI at 18 years respectively. These charts are thus most appropriate for non Asian children of the world.

WHO however recommends that for adult Asian Indians the BMI cut off value for overweight should be 23 and for obesity 28. It is thus important that based on the models such as IOTF, cut off standards for BMI at 23 and 28 adult equivalent are produced to screen Indian children for overweight and obesity from 5 year onwards (Below 5 years WHO MGRS has defined the cut offs already). We therefore constructed BMI charts with adult 23 and 28 equivalent cut offs for Indian boys and girls. These were validated against a total of 250 children from schools and a tertiary care pediatric clinic. The children were distributed over the whole range of BMI categories (adult equivalent BMI of <23, 23-25, 25-28, 28-30 and >30) (mean age 11.4 ± 2.9 years). Forty-three percent children in the adult equivalent BMI category of 23-25 had one or more than one risk factor for development of the metabolic syndrome (MS). Similarly, 73 percent children in the BMI category of adult equivalent of 28-30 had one or more than one risk factor for developing the MS and would be classified as overweight rather than obese if an adult equivalent cut-off of 30 were to be used. This validation suggests that Indian children above the adult 23 cut off are already showing risk factors for development of metabolic syndrome and hence it is appropriate to use these cut offs for screening children who are at increased risk of later development of metabolic syndrome.¹²

Thus with these two recent studies contemporary cross sectional reference percentile curves for height, weight and body mass index (adjusted for the Asian adult BMI equivalent cut offs) for the assessment of physical growth

of present day Indian children are thus made available for clinical use and for research purpose.

SHORT STATURE

Introduction

Short stature is one of the common problems in Pediatric practice for which an endocrinologist's opinion is sought. Short stature is not a diagnosis by itself but a presenting symptom of a variety of systemic, genetic and hormonal disorders. Short stature can sometimes be the only symptom of systemic or endocrine disease and a high index of suspicion and good diagnostic acumen are needed to reach the etiological diagnosis. A systematic approach is often the key to reduce the need for a whole battery of tests, which are often expensive and unnecessary.

Definition

A child is considered to be short in stature when his/her height is below the third percentile on a distance growth chart for the specific population. It is important to use country specific growth charts so that appropriate population standards are applied and over diagnosis of short stature is avoided. While using growth charts parents' heights should be considered and mid parental height plotted.

Use of Growth Charts

Distance height charts, height velocity and proportion charts are essential tools in the diagnosis of short stature. When height velocity observed over a period of 6 months or more falls below 25th percentile on the velocity chart, it is considered abnormal and more significant than a single height reading below the 3rd percentile on a distance chart. Growth velocity is a very sensitive and reliable way to decide whom to investigate. Proportion charts consist of sitting height and subischial (SIL) leg length. These are expressed as standard deviation scores and not as percentiles. When the disproportion between SIL and sitting height is more than 2 z scores, the child is considered to be disproportionate. As a primary screening tool distance charts are useful and when a short child is detected, velocity charts are used to follow his/her progress over a period of time.

Target Height and Familial Short Stature

Parents' height should be taken into consideration so that height of the child can be properly interpreted for the family's genetic potential. The formula used for calculation of target height (TH) is (Mother's height + Father's height divided by 2) + 6.5 cms for a boy and - 6.5 cms for a girl. This value is then plotted as adult height at 18 years and the spread is 6 cms on either side of the TH. This then is the target range and if the child's height is within these percentiles it is taken as normal. Auxological data

mainly TH, child's current height, height velocity and body proportions are some of the most important tools for proper evaluation and management of short stature. Proper use of these techniques will reduce the cost of subsequent tests.

ETIOLOGY

Common causes of short stature seen in India are as follows:

- Chronic malnutrition
- Chronic systemic disease
 - Chronic infections such as tuberculosis
 - Chronic renal failure
 - Cardiac disease
 - Respiratory disease such as asthma
 - Collagen vascular disease, JRA, etc.
 - Inflammatory bowel disease
- Familial short stature
- Chromosomal abnormalities and syndromes
- Endocrine disease
 - Hypothyroidism
 - Growth hormone deficiency and GH resistance syndromes
 - Cushing syndrome
 - Delayed puberty

The proportion of etiologies for short stature in Indian referral centers is familial short stature (20%), systemic disease (10-20%), syndromes and skeletal dysplasia (10-19%), Turner syndrome (7-10%), growth hormone deficiency (15%), hypothyroidism (5-10%) and constitutional delay of growth and puberty in 10-15 percent.¹³

Clinical Clues

ICP model of growth: The infancy childhood puberty model of growth suggest that during infancy the main determinant of growth is nutrition, during childhood years it is thyroxine and growth hormone and during puberty it is sex steroids. Based on this model if the growth failure starts for the first time in infancy nutritional deficiency is the likely cause, where as if it starts in childhood hypothyroidism or GH deficiency are more likely. Growth failure first time at the time of adolescence is usually due to disorders of puberty and commonest being constitutional delay of growth and puberty¹⁴ (Fig. 2).

Certain clinical clues are useful to reach the diagnosis and are summarized in the Table 3.

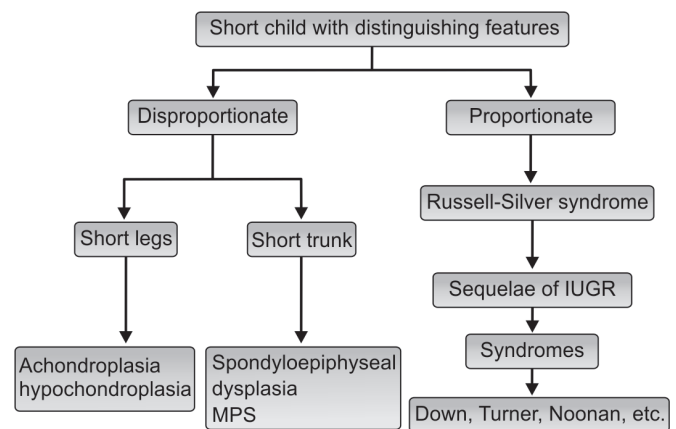

Besides the above mentioned features pathognomonic clinical signs can be seen in syndromes such as Russell Silver, Down or Turner.

In a disproportionately short child, short limbs usually suggest skeletal dysplasia such as Achondroplasia or hypochondroplasia where as short spine suggests a metabolic defect such as Mucopolysaccharidosis (Flow chart 1).

Table 3: Clinical clues to etiology

Clue	Etiology
Disproportion	Dysplasia, rickets
Dysmorphology	Syndromes, hypopituitarism
Frontal bossing, micropenis	GHD
Goiter, coarse skin	Hypothyroidism
Obesity, buffalo hump	Cushing syndrome
Short metacarpals	Turner, SHOX, pseudohypoparathyroidism
Ophthalmic problems	Pituitary tumor, craniopharyngioma, Septo-optic-dysplasia

Flow chart 1: A short child with distinguishing features

Height age and weight age: In a short child who is also thin, height age higher than weight age suggests chronic malnutrition or chronic systemic disease where as weight age higher than height age (short and fat) suggests a hormonal disease such as GHD or hypothyroidism.

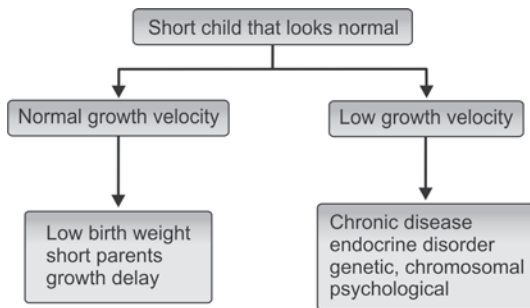

Tanner sexual maturity rating (SMR): Growth disorders that manifest around puberty are often caused by delayed puberty. One of the most important clinical clues to reach the diagnosis of puberty disorders or endocrine disorder is sexual maturity rating. As a routine, Tanner SMR staging should be done in all children who manifest with short stature.

INVESTIGATION

The algorithm given above (Flow chart 2) helps in deciding which investigations are necessary. Following is a brief interpretation of these tests.

Commonly done investigations are as follows:

1. Hemogram, ESR
2. S. creatinine, urea
3. Liver function tests
4. Bone age, skull X-ray
5. Tissue transglutaminase
6. Thyroid function tests

Flow chart 2: A short child that looks normal

values below 7 ng/dl on a stimulated sample are considered to be low suggesting GH deficiency.

Newer tests for diagnosis of GH deficiency are insulin like growth factor 1 (IGF-I) and insulin like growth factor binding protein 3 (IGF BP3). IGF-I is influenced significantly by nutritional status and but BP3 is not and two together are a better guide for the diagnosis of GH deficiency.¹⁵

In a recent review of all the available methods for diagnosis of GH deficiency, it is suggested that IGF-I, BP3 and neuroimaging as a combination is a more reliable way of diagnosis GHD particularly when combined with genetic studies.¹⁶

Neuroimaging

A plain X-ray of the skull may show a wide sella and calcification suggesting a space occupying lesion but does not give much information about the anatomy of the pituitary gland. MRI remains the best neuroimaging modality to diagnose pathology of the pituitary gland and hypothalamic area.

TREATMENT OF SELECT CONDITIONS

Chronic Disease and Malnutrition

Chronic malnutrition is treated by nutritional supplements and chronic disease such as chronic renal failure or ulcerative colitis will need appropriate management of the condition. As the condition improves the child will gain height and no specific treatment for the short stature is necessary except in chronic renal failure where growth hormone will improve the final height.

Hypothyroidism

Thyroxine is needed for physical growth and juvenile hypothyroidism may only manifest with short stature. The treatment consists of replacement therapy with levothyroxine in a dose of 100 mcg per meter square per day. Children show good catch up growth with treatment but often fail to achieve their genetic potential due to the time lost from development of disease to starting of therapy. The treatment of juvenile hypothyroidism is usually for life and regular monitoring is necessary.

Growth Hormone Deficiency

GH deficiency can be due to variety genetic defects. It can be isolated or in combination with other hormonal deficiency. Acquired causes are usually due to intracranial space occupying lesions or it's treatment in the form of surgery, radiation and chemotherapy. The dose of GH used for treating classical GHD is 20-30 $\mu\text{g/kg/day}$ for several years. It is possible to achieve a normal height after years of GH replacement therapy. GH remains a very expensive medication and the cost of therapy is often the limiting factor in continuation of therapy in India.

7. GH stimulation tests
8. IGF-1, IGF – BP3
9. Neuroimaging – MRI
10. Karyotype and DNA studies

Bone Age

The methods used for calculation of bone age are Tanner Whitehouse and Grulich and Pyle. The bone age is a very useful, cheap and reliable tool for the assessment of short stature. When the bone age is retarded or advanced by 2 years or more it is abnormal and usually suggests an endocrine disease such as hypothyroidism, growth hormone deficiency or Cushing disease. In children who have chronic systemic disease or delayed puberty, bone age is delayed but not as much as in endocrine deficiency.

Karyotype/DNA Analysis

Turner syndrome does not always manifest with characteristic features but may only present as short stature. It is therefore important to check Karyotype in a girl with unexplained short stature. Recently a heritable form of genetic defect, the SHOX gene defect has been described in short children, which leads to a heritable form of short stature, short 4, 5 metacarpals, bowing of forearm bones and exostosis. This condition has been shown to respond to GH therapy. Similarly conditions such as Down syndrome, Prader Willi syndrome can be detected by chromosomal/DNA analysis.

Test for Growth Hormone

One of the most difficult tests in terms of interpretation and reproducibility is the GH stimulation test. A non-stimulated fasting GH does not give much information and should be avoided. GH should be checked after stimulation with either Clonidine, l-dopa, Glucagon, arginine or insulin induced hypoglycemia. The last test can be dangerous and should be avoided in young children. Even stimulated GH is not always reliable and hence newer tests are being invented. Some experts recommend priming the patient with sex steroids before GH stimulation test especially in peripubertal children. Growth hormone

Other uses of Growth Hormone

In 1985 recombinant GH became available and since then its use has been expanding with newer and newer indications being added to the list of conditions for which it is already licensed. At the present time growth hormone is approved for use in growth hormone deficiency, Turner syndrome, chronic renal failure, SGA who fail to catch up by 2 years and severe familial/idiopathic short stature. It is also being evaluated in conditions like Prader Willi Syndrome, Noonan syndrome, skeletal dysplasia, etc. Growth hormone is generally a well-tolerated medication with a few known side effects viz. headaches and benign intracranial hypertension, water retention, glucose intolerance and rarely slipped capital femoral epiphyses, gynecomastia and local reactions.

In conclusion, the diagnostic ability and treatment avenues for short children are ever expanding. A systematic and analytical approach is the key to the etiological diagnosis and successful management of short children.

Growth Hormone Therapy

Archana D Arya

INTRODUCTION

Human growth hormone (hGH) was first used in 1950's to stimulate growth in children with hypopituitarism.¹ It was obtained by purifying cadaveric pituitary extract, and hence the availability was limited. In 1985 the first case of Creutzfeld-Jacob disease was reported in a patient who had received growth hormone and subsequently more cases were reported. The preparation was banned and in the same year,² the 192 aminoacid biosynthetic GH was approved by the food and drug administration (FDA), USA. Since then there has been abundant supply of the recombinant rhGH.

Benefits of GH therapy in GH deficient children have been well documented, but since the recombinant GH preparation has been available, its growth promoting effect in children who do not have classical GH deficiency has been investigated in a large number of children. Now it is also being studied for its metabolic effects besides the effect on linear growth. The paradigm has shifted from GH replacement to GH augmentation therapy. The number of FDA approved indications has more than doubled in the last 5 years. This has made the decision about GH use for short stature, more complex. There is a concern about short children developing psychological problems, but data to support that improvement in height would improve psychological health is scarce, except in severe GH deficiency.³

PHYSIOLOGY OF GROWTH HORMONE

Human growth hormone is secreted by the anterior pituitary gland. Growth Hormone Releasing Hormone (GHRH) stimulates the secretion of GH and somatostatin inhibits it. Both GHRH and somatostatin are synthesized by the hypothalamus.

The secretion of GH is cyclical and pulsatile, and it is released in response to sleep, exercise and hypoglycemia. It

is bound to GH binding protein in the circulation and has a short half-life of less than 20 minutes. Due to the pulsatile secretion and short half-life, frequent sampling is required to identify peaks. Hence GH response to pharmacological stimuli is used for judging adequacy of secretion.

Growth hormone mediates its effects through insulin like growth factor I (IGF-1), which is a peptide secreted by the liver in response to stimulation by GH. It is bound in the circulation to IGF binding proteins (IGFBP) the most important one being IGFBP-3.

Insulin like growth factor-1 (IGF-1) levels correlate with the clinical state of GH deficiency, sufficiency or excess but do not exclusively reflect GH production because levels of IGF-1 vary with age. Insulin like growth factor-1 correlates better with bone age and puberty rather than chronological age. Poor nutrition and chronic disease may decrease the IGF-1 levels.

EFFECTS OF GROWTH HORMONE

The most apparent effect of GH is to stimulate linear growth in children before epiphyseal fusion occurs. Besides this it has a number of other metabolic effects:

- Anabolic (Cell proliferation and protein synthesis)
- Lipolytic (Decreases adipose tissue)
- Increases lean tissue
- Increases bone density
- Bolsters cardiac contractility
- Improves mood and motivation
- Increases exercise capacity
- Alters the carbohydrate metabolism

INDICATIONS OF GROWTH HORMONE THERAPY

The FDA, USA has approved the following indications of GH therapy:

GROWTH HORMONE DEFICIENCY

Growth hormone has been used for GH deficiency (GHD) for almost 50 years now. The tests that have been used for diagnosing GHD are not physiological, are expensive, invasive, may be risky and results are not reproducible very often. The cut offs have also been arbitrary and have changed from <7 to <10 ng/ml over the last few years. Provocative tests are fairly accurate for diagnosing complete GH deficiency, but are not good for distinguishing between partial GH deficiency and normal short stature.

The gold standard for diagnosing GHD was to demonstrate inadequate GH stimulation with 2 pharmacological agents. Growth hormone level of <10 ng/ml on provocative stimulation is suggestive of GH inadequacy. As more children were tested for GH insufficiency, it was observed that about 20 percent children with normal stature show stimulated levels of <7 ng/ml and a large number of short children had normal levels of GH on stimulation. It is likely that these children are not able to secrete sufficient amounts of GH to sustain normal growth. Hence auxological parameters are far more important than provocative testing for making a diagnosis of GHD¹¹ and the onus of this lies with the pediatrician, who should monitor height and weight of children regularly. Due to these observations the diagnostic criteria for GH deficiency have changed over the years.

The Growth Hormone Research Society recently recommended measurement of IGF-1 and IGFBP-3 in addition to provocative GH testing to identify children with abnormalities in the GH/IGF axis not detected by standard tests.

Children with GH levels in the high subnormal range and with normal stimulated levels but low spontaneous secretion or low IGF-1 and IGFBP-3 are now considered to have partial GH deficiency.

An MRI of the brain for hypothalamic-pituitary region should be done prior to initiating therapy to rule out an anatomical defect or presence of a mass.

Early initiation of treatment with GH, in cases with growth hormone deficiency results in normal adult height.⁴

Recommended dose of GH in children with GHD is 0.07 to 0.1 IU/kg or 0.21 to 0.3 mg/kg day. Daily dose results in better growth than thrice-weekly injections. The best response is seen during the first year of treatment.

Turner Syndrome

The longest trials of GH therapy, after GHD have been on girls with Turner syndrome. Turner syndrome (TS) occurs because of the complete deletion of an X chromosome or a part of one of the arms. Mosaicism may occur in this condition. 95 to 100 percent of these girls have growth retardation and untreated their height is about 143 cm as reported from the western literature, which is about

20 cm less than their average height. Turner girls also have hypogonadism due to ovarian dysgenesis, which worsens their short stature.

Special growth charts are available for girls with Turner syndrome.

Short stature in Turner girls is due to the combined effect of aneuploidy, primary skeletal dysplasia, mild GH secretory dysfunction and estrogen deficiency. The SHOX (short stature homeobox containing gene) gene is located in the pseudoautosomal region of the short arm of the X chromosome. Haplo-insufficiency of the SHOX gene due to deletion of part of X chromosome results in short stature and skeletal abnormalities in TS.

Turner girls usually fall below the 3rd percentile of the growth chart after the age of 7 years leading to a delay in diagnosis. By the age of 9 years most girls are below the 3rd percentile. Due to hypogonadism there is no pubertal growth spurt, hence there is worsening of short stature by the age of 13 years. These girls are at a higher risk of developing thyroid and celiac disease and presence of any of these would worsen the short stature. Both these conditions should be ruled out prior to initiating therapy. Since these girls are usually not GH deficient once a diagnosis of TS has been made, provocative testing for GHD is not required.

Growth hormone therapy with or without anabolic steroids like oxandrolone accelerates growth in girls with TS.⁵ Studies have shown that the mean final height of girls with TS treated with GH was 150.4 cm, which was about 8.4 cm more than the expected average height and those treated with GH and oxandrolone was 152.1 cm, which was 10.4 cm more than the predicted height without treatment.⁶

At this time initiation of therapy is recommended as soon as females with TS have dropped below the 5th percentile of the normal female growth curve. This could be as early as 2 years of age. Final height improves by about 12 cm if GH therapy is started by 7 years of age. Treatment after 12 years of age improves final height by only about 5 cm. Hence GH should be started at a younger age for a good response.

The recommended starting dose is 0.05 mg/kg/day. Sas et al¹² treated 68 girls with Turner syndrome (mean age 6-7 years) who were randomly assigned to three different regimens of growth hormone. The girls attained normal adult height (mean values 159-162 cm).

Escalating doses over time above the initial 0.05 mg/kg per day resulted in a 2 to 3 cm greater increment in growth, although the safety of this approach is not known. These excellent height results were achieved after average treatment duration of seven years.

In older girls or those >8 years of age if therapy is started when short stature is extreme, concomitant administration of oxandrolone should be considered. Routine use of oxandrolone is not recommended. It should be reserved for those in whom GH therapy is delayed, in very low doses to prevent

virilization. Monitoring of GH therapy should be done as for any other child on GH therapy.

Timing of hormone (estrogen) replacement therapy (HRT) for hypogonadism, in Turner girls is very important, since HRT results in acceleration of bone maturation and epiphyseal fusion. Hormone replacement therapy should be initiated in a manner so that it does not hamper the growth potential and on the other hand does not result in poor bone mineralization.

Chronic Kidney Disease

Growth failure is often the presenting symptom of chronic kidney disease (CKD). The genetic height potential is usually not attained in these children and the mean adult height is 2 standard deviations below the mean.

Poor growth in children with CKD is due to non-endocrine factors like malnutrition, acidosis, and renal osteodystrophy and endocrine factors such as GH resistance suggested by exaggerated response on provocative stimulation, decreased levels of IGF-1 and increased levels of IGFBP-I.

Despite dialysis, growth failure persists in these children and post-transplant, growth rate may normalize, but no catch up growth is seen.

Pharmacological doses of recombinant human GH (rhGH) corrects height deficit in most children with CKD before transplant. Growth hormone reverses the hypercatabolism in CKD and increases circulating IGF bioactivity that may result from the differential action of rhGH on plasma IGFs (significant increase) and inhibitory IGF binding proteins (no major change). The end result is an increase of IGFs in extravascular fluids that interact with the Type 1 IGF receptor for stimulating longitudinal growth.¹⁹

In a study of 38 children with CKD, GH treatment resulted in a final height that was 1.4 SD above standardized height at baseline and the mean final height of 50 non-treated matched control children with CRF was 0.6 SD below standardized height at baseline.⁷

The Cochrane database¹³ reviewed 15 randomized control trials involving 629 children to evaluate the benefits and harms of rhGH treatment in children with CKD. They concluded that 1 year of rhGH treatment at a dose of 28 IU/m²/week in children with CRF resulted in a 3.80 cm/y increase in height velocity above that of untreated patients. Trials were too short to determine if continuing treatment resulted in an increase in final adult height. The frequency of reported side effects of rhGH were similar to that of the control group.

Seikaly et al¹⁴ evaluated the utilization and potential benefits of rhGH in children with CKD and following renal transplantation in a large patient cohort. They queried the chronic renal insufficiency (CRI), dialysis, and transplant

registries of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) to characterize the frequency of rhGH utilization, factors related to its usage, and the relationship between rhGH usage and catch-up growth.

The analysis revealed that of 6505 children with CKD, 22 percent received rhGH. Recombinant human GH therapy was associated with catch-up growth in 27 percent of treated patients in this group.

Of the 5122 children on dialysis, 33 percent received rhGH, of which 11 percent patients showed catch-up growth.

Of the 4478 children who received a renal transplant, 3 percent received rhGH and catch-up growth was seen in 25 percent of treated patients.

In all groups, the highest catch-up growth was seen in patients in Tanner stage 1 or 2 of puberty.

In another study by Seikaly et al¹⁵ of children with chronic renal insufficiency who were treated conservatively (i.e. not on dialysis and had not received a renal transplantation), 787 children treated with rhGH were matched to 787 control patients who did not receive any GH by age, gender, height, and length of time on the registry. The estimated GFR of the treated group was less than the control group (37.5 versus 42.3 ml/min per 1.73 m²) and the height SDS were similar (-2.29 ± 0.04 and -2.23 ± 0.04). At the end of two years, the height SDS of the rhGH-treated group was 0.56 greater than the control group (-1.46 versus -2.02).

Growth hormone also appears to be effective in infants and growth-retarded pubertal children after renal transplantation. In addition, limited data from patients with CKD suggest that GH therapy may also improve bone metabolism.^{16,17}

A study of 10 prepubertal patients with CKD showed that rhGH therapy for 1 year produced a significant increase in lumbar spine and total body bone mineral content and bone mineral density.¹⁸

Studies on the use of rhGH in CKD suggest that:

- Children with preterminal CRF appear to respond better to rhGH than those on dialysis.
- Recombinant human GH therapy should be initiated at a young age with the goal of restoring the level of growth to a normal genetic percentile well before the need for renal transplant.
- Therapy should be instituted when the patient falls below the 3rd percentile for height and does not show spontaneous catch-up growth after other factors contributing to uremic growth failure have been adequately stabilized.
- The dose of rhGH in children with CKD is 0.045 to 0.05 mg/kg per day.
- Therapy is continued until final height is reached or a well-functioning renal transplant is achieved.

- Aim for a minimal height greater than the third percentile of the general population.
- Treatment of growth retardation after renal transplantation appears promising but is still experimental.
- Current information suggests no adverse effect of GH on the glomerular filtration rate.
- Growth hormone therapy is approved for treatment of children with growth failure associated with CKD, up to the time of renal transplantation and it should be used in conjunction with optimal management of CKD.

Prader-Willi Syndrome

Prader-Willi syndrome (PWS) occurs due to deletion in chromosomal region 15q11-13. The incidence is 1:10,000-25,000 live births. This condition is characterized by hypotonia, hyperphagia leading to gross obesity, short stature that is often due to GH deficiency, hypogonadism and psychomotor retardation. They typically have small hands and feet and almond shaped eyes.

Scoliosis is common in PWS. These patients are also at an increased risk for hip dysplasia and lower limb alignment abnormalities. Unlike other children with obesity, they do not appear to have increased risk for slipped capital femoral epiphysis.²⁰

They are also at a higher risk of developing complications such as gastric distension and rupture, sleep apnea and choking episodes.

Growth hormone therapy is recommended for children with PWS who have associated GH deficiency. Several clinical trials have demonstrated beneficial effects of growth hormone treatment on linear growth.²¹⁻²⁴ Body composition, including fat-free mass and bone density abnormalities, also appears to improve with growth hormone treatment.

Use of growth hormone for children with growth failure and genetically confirmed PWS was approved by the US FDA in 2000, and has been approved for this use in most countries.

Most individuals with PWS will have growth hormone deficiency when formally tested. Criteria for diagnosis of GH deficiency are the same as in other children. Nonetheless, it is generally not always necessary to evaluate formally for growth hormone deficiency before considering growth hormone treatment for patients with PWS and growth failure. IGF-1 and IGFBP-3 may be measured for adjusting doses of GH.

In USA use of GH in PWS indication requires growth failure.²⁵ Many studies have investigated the effect of rhGH on linear growth, body composition and bone density in children with PWS, and virtually all have demonstrated beneficial effects.^{21,22}

The optimal age to begin treatment, dosing, and duration of therapy has not been established.

Eiholzer et al²⁶ assessed the body composition of 11 infants with PWS <2 years of age by using deuterium dilution and investigated the efficacy of early institution of rhGH therapy in increasing lean mass (LM) and preventing massive obesity.

This group was compared before and during 30-month rhGH therapy (GH group) was compared with 6 infants administered only coenzyme Q (10) for 1 year (Q10 group).

They found that initially, LM (Ht) of all patients was below the normal average. They concluded that diminished LM (Ht) found in infants with PWS further declines during the early years. Early institution of GH therapy lifts LM (Ht) into the normal range and delays fat tissue accumulation.

Similar improvements in body composition with rhGH were reported in a randomized, placebo-controlled trial of 29 infants and toddlers with PWS (aged 4-37 months).²⁷ Initiating treatment before the age of 18 months was associated with accelerated acquisition of mobility skills compared with controls of the same age.

The response to GH in children with PWS is greatest during the first 12 months of therapy.²¹ Nevertheless, patients have had continued improvement in linear growth, bone density, and body composition when GH has been administered in sufficient doses for as long as five years.²⁸ Even with long-term growth hormone treatment, body composition is not completely normalized.

It results in growth rate increases similar to those seen in other GH deficient children. Growth hormone has additional positive metabolic effects in these children. It improves the muscle tone, decreases the fat mass, increases the lean body mass and bone mineral density⁸ in these children. Growth failure related to PWS is an approved indication for GH treatment.

Safety of rhGH in PWS: There have been reports of a few fatalities worldwide coinciding with the use of rhGH in children with PWS.²⁹ The deaths were associated with respiratory problems and/or were unexpected, and most occurred within the first three months of rhGH treatment. The patients had one or more of the following risk factors: severe obesity, sleep apnea, or respiratory infection.

It is unknown if the deaths were related to rhGH since children with PWS have an increased risk of sudden unexpected death independent of treatment with growth hormone.^{30,31}

Recombinant human GH may have effects on sleep-disordered breathing

Growth hormone may stimulate adenotonsillar hypertrophy via IGF-1 signaling. This mechanism is supported by case reports that correlate worsening obstructive apnea in some patients with higher IGF-1 levels.³²

On the other hand growth hormone may act directly on the hypothalamus and improve central hypoventilation.

This mechanism is consistent with observations that, in the majority of patients with PWS, growth hormone improves sleep-disordered breathing and/ or pulmonary function.³²⁻³⁴

Growth hormone therapy is contraindicated in patients with Prader-Willi syndrome who are severely obese or have severe respiratory impairment.

Pretreatment evaluation—rhGH therapy should be avoided in severely obese PWS patients. (e.g. >225 percent of ideal body weight).

Polysomnography should be done prior to initiating treatment and if an abnormality is found it should be treated prior to initiating therapy. Monitoring with polysomnography should be done during therapy and if there are signs of upper airway obstruction or sleep apnea, treatment should be discontinued.

Patients should be monitored with glucose tolerance tests prior to and during treatment and for scoliosis if present.³⁵⁻³⁸

The child should be evaluated for upper airway obstruction or apnea before starting growth hormone treatment and GH treatment should be interrupted if patients develop signs of upper respiratory obstruction (including onset of or increased snoring) and/ or new onset of sleep apnea. In addition, patients should be monitored for adverse progression of glucose tolerance and scoliosis.

We suggest that all patients with PWS undergo polysomnography prior to beginning growth hormone treatment. Growth hormone treatment should not proceed until the sleep disordered breathing is effectively treated. Those with abnormal polysomnograms should have follow-up studies approximately one month after beginning GH treatment, and all patients with PWS on GH treatment should be clinically re-evaluated if they develop intercurrent upper respiratory tract infections or increased obstructive symptoms. Particular care should be taken in managing this issue in infants and toddlers, who appear to be at the highest risk for respiratory compromise because of underlying hypotonia. For these children, we suggest monitoring oxygen saturation during sleep for the first one to two months after starting GH treatment, if possible.

Small for Gestation

Small for gestation (SGA) is defined as a birth weight or length, more than 2 SD below the mean (Birth weight <2.5 kg of a baby >37 weeks gestation). Three to ten percent neonates are born small for gestation (SGA). This usually occurs because of intrauterine growth retardation (IUGR). After birth majority of these infants show good catch-up growth and normalize their height and weight. About 10 percent of them continue to remain short (<-2SD) and do not achieve normal adult height, resulting in psychosocial problems.

Small for gestation infants usually have low levels of insulin, IGF-1 and IGFBP-3 at birth. Levels of these

hormones rise in the babies who show catch-up growth. Infants who do not show catch-up growth usually have an alteration in the GH-IGF-1 axis that is poorly understood. An irreversible deficit in cell number, inadequate calorie intake during the first year of life, may contribute to the lack of catch-up growth.

Classic GH deficiency rarely is found in these children, however there may be subtle abnormalities in the GH secretory pattern similar to those documented in adults during prolonged critical illness.³⁹

Initial trials with GH therapy did not show a good response probably because low doses of GH were used and administration of the drug was infrequent. A number of multicenter trials have been carried with GH therapy for SGA babies who do not show catch-up growth, over the last few years. Growth hormone was used irrespective of their GH status. Both high and low dose GH and continuous and discontinuous treatments have been used in these children. These studies conclude that:

- Growth hormone therapy in short SGA children with no catch-up growth normalizes adult stature and results in an adult height that is within the target range.
- Better adult height is achieved if treatment is started at a younger age, although some improvement in adult height is found even if treatment is started during adolescence.
- Both, low dose continuous and high dose discontinuous treatments are almost equally effective.
- Growth hormone therapy is equally beneficial in GH deficient and non-GH-deficient SGA children.⁹
- Long-term GH treatment normalizes adult height (AH) (above -2 SDS) in 85 percent children, and 98 percent achieve an AH within their target height range.

The US FDA has approved GH therapy for the treatment of growth failure in children who are born SGA and do not achieve catch-up growth, i.e. height remains less than 2 SDS below the mean for age and sex at 2 years of age⁴⁰ at dosages up to 0.48 mg/ kg/week.

In Europe, the approved indication is for short SGA children whose height is less than 2.5 SDS below the mean for age and sex at 4 years of age.^{41,42} In addition, the European indications include low growth velocity (i.e. height velocity less than average for age) and predicted height (>1 SD below mid-parental height).

Treatment is reasonably safe with no significant side effects. Short children born SGA are at increased risk for diabetes and cardiovascular disease when compared to children with normal birth weight. Whether treatment with growth hormone either improves or exacerbates these long-term risks has not been established. However, there appear to be no difference in the short-term risks of GH treatment in this population as compared with other children treated with growth hormone. The risk of

developing accelerated bone maturation is minimal with high or low doses of GH.

IDIOPATHIC SHORT STATURE

Short children whose heights are two standard deviations (SD) or more below the mean for age, i.e. 3rd percentile, who have no demonstrable functional abnormality (no endocrine, metabolic, or other diagnosis) and whose parents are normal in height are considered to have idiopathic short stature.^{43,44} It is suspected that these children/adolescents have an abnormality of the GH-IGF axis that cannot be detected by biochemical testing or there may be underlying genetic defects in these individuals that may not have been identified at this time. Mutations in the SHOX gene are responsible for up to 4 percent of cases of apparent "idiopathic" short stature.

A recent study of 80 non-GHD children treated with GH showed a mean increase in SD score for height from -2.7 to -1.4. The mean difference between the predicted adult height before treatment and achieved adult height among boys was 5.0 ± 5.1 cm and 5.9 ± 5.2 cm for girls. Only a few subjects in this study reached their mid-parental height.¹⁰ It seems that long term GH treatment of non-GHD children can lead to statistically significant increases in final height in some children. Several similar studies have demonstrated that growth hormone therapy generally increases height velocity acutely and may increase adult height in children with ISS. Growth hormone therapy for these children was approved by the US FDA in 2003. The indication is for children with current height below -2.25 SD of the mean, in whom the epiphyses are not closed, and whose expected adult height is less than 63 inches (160 cm) for boys and 59 inches (150 cm) for girls.

Growth hormone therapy in children with ISS is still controversial despite being approved. The reasons for controversy are that:

- A majority of children with short stature will experience some catch-up growth during puberty without GH treatment. Despite improvement in final height the adult height was 5 to 6 cm below target height.⁴⁵
- Other studies report a spontaneous increase of between 0.5 and 1.9 SD in untreated children.⁴⁶
- There is little evidence that short stature has a detrimental effect on an individual's psychosocial or physical functioning.
- It is difficult to predict responsiveness to GH treatment, due to the clinical and molecular heterogeneity of the condition and also the inconsistent criteria for ISS and GH treatment doses used in clinical trials.⁴⁶⁻⁵⁰
- The available evidence suggests only modest efficacy for GH treatment in children and adolescents with ISS, which must be weighed against the potential adverse

financial, psychosocial, and physiological effects of the treatment.

Other conditions for which GH is being used often are:

- Skeletal dysplasias esp. hypochondroplasia
- Thalassemia major
- Hypophosphatemic rickets
- Patient's on chronic glucocorticoid therapy (juvenile rheumatoid arthritis, asthma)
- AIDS wasting (FDA approved)
- Adult GH deficiency (FDA approved)
- Slow growth in children on LHRH analogs for precocious puberty

Conditions in which GH therapy has been investigated, but not used routinely:

- Familial short stature
- Constitutional growth delay
- Syndromes (Noonan's, Down's)
- Cystic fibrosis
- Postoperative wound healing
- Burns
- Inflammatory bowel disease
- Aging

DOSAGE AND MONITORING OF GH THERAPY

The dose of growth hormone used varies according to the condition being treated. Pharmacological doses are 0.07 to 0.1 u/kg/day. Higher doses are used in certain conditions such as Turner syndrome and SGA. Higher doses have also been used during puberty to improve adult height. IGF-1 based dose of GH is also being used by some clinicians. GH dose should be adjusted to maintain IGF-1 within a normal range. The GH dose is adjusted to keep the IGF-1 level at approximately 1 SD above the mean for age and gender. If IGF-1 levels are consistently elevated (>2.5 SD), the GH dose should be reduced.⁴⁴ IGF-1 levels should be checked approximately four weeks after beginning therapy or changing the GH dose, and approximately every 6 to 12 months thereafter, similar to the approach used for patients with GH deficiency.

It is given as a daily subcutaneous injection at night to mimic the timing of natural GH secretion. Growth with daily dosing is better than with thrice weekly doses, which were being used earlier. The preparation can be given with a pen device by the parents at home.

Routine monitoring of thyroid functions, blood glucose, IGF-1 and IGFBP-3 during therapy is recommended. Glucose tolerance test should be done in high-risk children. Cost of GH therapy is very high and is approximately Rs 18,000 per month for a child weighing 20 kg. Treatment should be continued till response to therapy is good or satisfactory height is achieved or till epiphyseal fusion occurs.

SIDE EFFECTS OF GROWTH HORMONE THERAPY

Side effects of GH therapy are listed below. They are not encountered very often but monitoring for side effects must be done regularly.

- Hypothyroidism
- Pseudotumor cerebri
- Slipped femoral capital epiphysis
- Possible salt and water retention
- Hyperinsulinemia
- Gynecomastia
- Growth attenuation from antibody formation

In the past there had been a concern about recurrence of malignancy/occurrence of new malignancies in GH treated patients. Prolonged follow-up studies indicate that the rates of new leukemia in patients without pre-existing factors who are treated with GH are not greater than the general population. There is also no risk of developing non-leukemic neoplasms or recurrence of malignancy in GH treated patients.

ETHICAL ISSUES IN GROWTH HORMONE THERAPY

Availability of recombinant Growth Hormone (GH) in abundance has resulted in a marked increase in its usage. Earlier the only indication for GH therapy was severe GH deficiency and the purpose was to normalize adult height of children who had severe growth retardation. In the last few years the diagnostic criteria for GH deficiency have changed and so have the cut off values, which has resulted in more and more children being treated.

Use of GH in non-GH deficient children has also increased with more indications being included and the aim is now to enhance normal stature very often. Although GH therapy is reasonably safe, a small number of children do develop permanent complications like diabetes, slipped capital femoral epiphyses, etc. The cost of GH therapy is also very high worldwide.

Keeping this in mind, GH therapy should be used only if it enhances the adult height in children who would otherwise be abnormally short and should not be used to improve normal stature.

There is no role of short-term GH therapy and it should only be used if the patient can afford treatment for a long enough period to normalize adult height.

Expectations should be realistic and the risks and benefits must be explained to the parents before starting therapy.

Precocious Puberty

S Srinivasan

Puberty is an important, transitional but critical developmental event in children's life, whereby these children attain physical and sexual maturation with reproductive capability. This orderly process results in the development of secondary sexual features, gonadal functional maturity and completes the final phase of linear physical growth with sex dependent changes in body composition and psychosocial maturation. An intact hypothalamic – pituitary – gonadal (HPG) axis is essential for the initiation and completion of puberty. Any interference in the functioning of this axis can result in temporary or permanent disorders of reproductive endocrine function. The HPG axis, active and functional during second half of fetal development and early infancy, enters a relative quiescent state, often referred to as the juvenile pause. The factors that mediate the juvenile pause and those that lead to increased gonadotropin-releasing hormone (GnRH) secretion at the onset of puberty are the keys to the regulation of pubertal timing.¹

MATURATION OF THE HYPOTHALAMIC-PITUITARY-GONADAL AXIS

In humans, maturation of the reproductive system occurs in a phasic manner in well-defined stages.

The first stage begins during fetal life and lasts until late infancy. In the first trimester of gestation, the presence of hypothalamic gonadotrophin releasing hormone (GnRH) and pituitary luteinizing hormone (LH) and follicular stimulating hormone (FSH) has been demonstrated. The development of the neuroendocrine system, responsible for regulation of the reproductive system, is heralded by the formation of gonadotrophin releasing hormone (GnRH) neurons in the rostral forebrain associated with the olfactory placode. These neurons migrate to an area in the arcuate nucleus of the hypothalamus destined to become the GnRH pulse generator. These neural cells

develop intrinsic and unregulated pulsatile activity by around 11 weeks of gestation. By midgestation the pituitary portal system is completed, thereby allowing transport of hypothalamic peptides to the pituitary. At 20 weeks of gestation, GnRH secretion is maximal and stimulates secretion of LH and FSH. In the male fetus, testosterone increase causes penile enlargement before birth. Later in gestation, this increase in gonadal steroids exerts negative feedback and begins to regulate the pulse generator.

The second stage starts from the time of delivery when the neonate is cut off from the placenta—the dominant source of estrogenic sex steroids. This withdrawal of the negative feedback results in raised levels of gonadotropins (LH and FSH) in episodic pulses until 4 to 6 months of age. This is responsible for a transient secondary gonadal stimulation occurring in the first months following birth. Although occurring in both boys and girls, this is observed most readily in female infants in whom there may be prolonged neonatal breast budding. After 6 months of age, these elevated plasma gonadotrophin and sex steroid levels decrease to low levels until the peripubertal period.

The third stage of maturation, termed the juvenile pause, begins at 6 months of age when gonadotropin and sex steroid concentrations fall to low levels. This stage is the period between infancy and puberty when hypothalamic GnRH is kept restrained in spite of low plasma concentrations of LH, FSH, and sex steroids by an additional inhibitory mechanism, suggested to be present in the central nervous system (CNS)/hypothalamus. Although mean serum concentrations of gonadotropins are low during the prepubertal period, the reproductive system is not totally inhibited as small spontaneous LH pulses occur at a low frequency in normal children.

The fourth stage is characterized by the reactivation of the reproductive axis, reactivation of GnRH secretory activity and activation of the cascade of pituitary-gonadal

maturation resulting in puberty. The mechanisms responsible for the initiation of pubertal events are extremely complex. They involve the integration of numerous different signals including attainment of a certain body mass or composition which is probably linked with levels of leptin, a hormone produced in the adipose cells. The effect of increased leptin levels on the initiation of puberty appears to be secondary to the suppression of the neuropeptide Y by leptin, thus releasing its inhibition of the pituitary gonadotropin axis. Leptin though considered necessary to initiate puberty is not the only factor. There is normal progression of puberty even with small amount of leptin, where as in its complete absence there will be absence of progression to puberty. At the time of puberty, leptin binding sites decrease, allowing small amount to exert greater effect. Neural signals derived from centers within the central nervous system that serve as a biological clock are also likely involved.

GONADARCHÉ

A striking increase in amplitude and frequency of LH pulses, especially at night, heralds the onset of puberty. These increases of LH precede rise of sex steroid concentrations and the development of secondary sex characteristics. As pubertal maturation progresses, similar increase in the amplitude and frequency of gonadotropin pulses occurs during the day until the final stage of sexual maturation is reached. Regular pulses of GnRH establish the mature pattern of gonadal steroid secretion during this period. The mechanism underlying the relative suppression and subsequent pubertal activation of hypothalamic GnRH is still to be elucidated. Pulsatile GnRH stimulates pituitary FSH and LH secretion, which in turn bind to ligand-specific receptors in the gonads, causing gonadal maturation and production of sex steroids, most notably testosterone and estradiol ultimately stimulating gametogenesis in males and females.^{2,3} This process is termed gonadarche.

Testosterone and estradiol, together with inhibin, activin, and follistatin, regulate the subsequent activity of the hypothalamus and pituitary gland. The transition from childhood quiescence to the adolescent pattern of GnRH secretion is a gradual process, and LH and FSH pulsatility has been detected in normal children as young as 4 years of age. In females, this results in the regular cyclical variations of gonadotropins, estrogen, and progesterone characteristic of the menstrual cycle. In the ovary, FSH stimulates follicular maturation and estrogen production through aromatization of androgens, whereas LH stimulates production by theca cells, triggers ovulation, and maintains progesterone production by the corpus luteum. In males, the same regular pulses of GnRH establish a pattern characterized by relatively constant levels of testosterone and gonadotropins, with minimal diurnal

variation. In the testis, FSH acts on Sertoli-Leydig cells to initiate spermatogenesis and LH acts on the Leydig cells to stimulate testosterone production.⁴

ADRENARCHÉ

The physical changes of puberty result from both gonadarche and adrenarche. Adrenarche refers to the maturation of the zona reticularis of the adrenal gland, resulting in increased production of adrenal androgens. This is associated with development of secondary sexual characteristics such as the pubic hair (pubarche), axillary hair, body odor, and acne. Adrenarche begins usually at the age of 8 years, but can occur as early as 6 years.^{5,6} The onset of adrenarche, like gonadarche, is a gradual and progressive maturational process that begins in early childhood and is marked by further increases in the production of adrenal androgens (DHEA, DHEA-S, androstenedione) around the time of puberty.⁷ Adrenarche may precede gonadarche by 1 to 2 years in boys and girls, but the timing of clinical signs can vary. Adrenarche and gonadarche often overlap, but they are separate processes that are regulated independently.^{8,9} The triggers for adrenarche remain unknown; however, the developmental process is likely to be modulated by the alterations in body weight and body mass index (BMI) besides fetal and neonatal physiology.^{10,11}

A variety of other hormones are also modulated with the onset and progression of puberty. As a result of increased sex steroid concentrations, sex hormone-binding globulin is lower during puberty than in childhood. While secretion of LH is inhibited by androgens and estrogens, the secretion of FSH is suppressed by gonadal production of inhibin, a 31-kd gonadal glycopeptide produced by the Sertoli and granulosa cells. Inhibin, consisting of α and β subunits joined by disulfide bonds, shows a progressive increase in mean concentration with advancing puberty in both sexes. The β - β dimer (activin) also occurs, but its biologic effect is to stimulate FSH secretion. The biologic features of these newer hormones are being delineated. In addition to its endocrine effect, activin has paracrine effects in the testis.¹² It facilitates LH-induced testosterone production, indicating a direct effect of Sertoli cells on Leydig cells. Concentrations of the glycoprotein anti-müllerian hormone (AMH) show marked sexual dimorphism. The AMH is produced in Sertoli cells and the levels are relatively high in newborn boys but are undetectable in girls. In contrast, the hormone becomes very low in boys during puberty, at which time AMH concentrations increase in girls.

Growth hormone (GH) spontaneously increases during puberty and the increase is more marked at nights. IGF-1 levels during puberty are higher than those of the adult and it has a role in the pubertal growth. Their levels do not correlate with the pubertal velocity of growth.

The role of genetic and chromosomal mutations in regulating the timing of puberty in healthy adolescents remains unclear. Pubertal timing is correlated highly within ethnic population groups, within families, and between monozygotic twins, with heritability estimates suggesting that 50 to 80 percent of the variation in pubertal timing is determined by genetic factors. Environmental factors also play a definitive role in the initiation of puberty. Diet, obesity and leanness, exercises and sports like athletics, gymnastics and ballet dancing are well-known factors in influencing the pubertal age and attainment of menarche.

There are interesting facts that are emerging with regard to chemical neurotransmitter peptides that regulate, control and initiate the pubertal development. In spite of voluminous information available, it is a fact that even today the exact mechanisms responsible for the initiation of normal puberty are not clearly understood.

PRECOCIOUS PUBERTY

Definition

Precocious puberty is a clinical state in a child, where the physical and hormonal signs of pubertal development appears at an earlier age than is considered normal—8 years in girls and 9 years in boys.¹³⁻¹⁷

The definition of precocious puberty as seen in the standard textbooks has been traditionally “development of secondary sexual characteristics” in girls less than eight years of age. In a cross-sectional study to assess breast and pubic hair development of 17,000 females, aged 3 to 12 years by Herman-Giddens and coworkers in 1997, girls in the United States have been found to undergo pubertal development at younger ages than previously reported.¹⁸ In white girls, the mean age for attainment of Tanner 2 breast development was 10.0 ± 1.8 years, while Tanner 2 pubic hair began at a mean age of 10.5 ± 1.7 years. In African-American girls, onset of puberty occurred even earlier, with a mean of 8.9 ± 1.9 years for Tanner 2 breast development and 8.8 ± 2.0 years for Tanner 2 pubic hair. Additionally, 6.7 percent of white and 27.2 percent of African-American girls had evidence of breast or pubic hair development before the age of 8 years, indicating that application of traditional definitions would result in a high proportion of girls being diagnosed with precocious puberty.

Kaplowitz and colleagues, having analyzed available studies on recent change, i.e. advancing age in the appearance of Tanner stage 2 breast development and stage 2 pubic hair in American girls,¹⁹ especially among blacks, have issued some guidelines for evaluation and treatment of girls with possible precocious puberty. In 1999, the Drug and Therapeutics and Executive Committees of the Lawson Wilkins Pediatric Endocrine Society (LWPES) published new recommendations suggesting the age cut-off for precocious puberty should be

decreased to 7 years in white girls and 6 years in African-American girls. In boys, there has been no such modification in the definition.¹⁴ This report not only suggested a change in the age limit but also recommended that white girls with breast development after age 7 or African-American girls with breast development after age 6 years should undergo evaluation if the tempo of pubertal progression is abnormal resulting in a bone age advanced more than two years and a predicted height that is either less than 150 cm (59 in) or two SD below the genetic target height; headaches, focal neurologic deficits, or an underlying neurologic problem are present; or the child's or family's emotional state is affected adversely by the progression of puberty and potential for early menarche.

The controversy with regard to the recommendations of LWPES of 1999 is that the implementation of the same by lowering the cutoff age would result in failure to identify young girls with underlying pathology. Several retrospective cohort studies have described cases of astrocytomas, gliomas, adenomas, craniopharyngiomas, hamartomas, congenital adrenal hyperplasia, and McCune-Albright syndrome that may have been missed using the new LWPES guidelines.²⁰⁻²² These data have led some to hold to the recommendation that all girls with pubertal onset before age 8 years have a complete evaluation including a head magnetic resonance imaging (MRI).^{23,24} Pending new data regarding normal age of pubertal onset and rates of pathology, most of the pediatric endocrinologists still perform a complete evaluation in all girls with pubertal onset younger than 6 years and in most girls with onset between the ages of 7 and 8.

Classification of Precocious Puberty

1. Central or GnRH dependent precocious puberty (CPP).
2. Peripheral or GnRH independent precocious puberty or precocious pseudopuberty (PPP).
3. Incomplete, unsustained, and intermittent forms of sexual precocity

Premature Adrenarche

Early appearance of pubic hair without breast development (girls) or enlargement of the penis or testes (boys). Although children with premature adrenarche (PA) typically grow at a normal rate, rapid growth was noted often enough, as discussed below, that this finding did not exclude a diagnosis of PA.

Premature Thelarche

Appearance of breast tissue (Tanner stage 2) in a girl under 3 years of age without evidence of rapid progression over time and no evidence of a central nervous system problem.

Table 1: Causes of central precocious puberty – (gonadotrophin –dependent)

<ul style="list-style-type: none"> Idiopathic (constitutional/functional) Central nervous system abnormalities 	
Congenital anomalies	Hypothalamic hamartomas, hydrocephalus, arachnoid cysts, suprasellar cysts, septo-optic dysplasia, meningomyelocele

Central (GnRH dependent) Precocious Puberty (True PP)

Central (GnRH dependent) precocious puberty (CPP), as the name suggests refers to those conditions where there is demonstrable premature activation of hypothalamic GnRH pulse generator- pituitary gonadotropin - gonadal axis resulting in earlier initiation and appearance of pubertal changes in children. Hence, in these conditions grouped under CPP, a pubertal type of pulsatile release of LH is seen with a similar increase in serum LH levels after GnRH administration as seen during normal pubertal development. GnRH dependent precocious puberty is always isosexual. The pace and pattern of advanced pubertal development varies depending on the cause of CPP. In complete CPP, ovulation and spermatogenesis are reported to occur. The causes of CPP are listed in Table 1.

GnRH independent - Peripheral Precocious Pseudopuberty (Table 2)

Here, extrapituitary source of gonadotropin or sex steroids is independent of premature activation of hypothalamic – pituitary - gonadal axis leads to earlier appearance of pubertal features (Table 2).

In gonadotrophin independent – Peripheral precocious pseudopuberty (PPP), sexual maturity may be either isosexual or heterosexual with only some of the features appearing early. The diagnostic criteria for PPP are:

Table 2: Causes of peripheral precocious pseudopuberty

(Gonadotrophin independent)	
Females isosexual (Feminization)	Males isosexual (Masculinization)
1. Ovarian tumors	1. Primary Leydig cell hyperplasia
2. Granulosa-theca cell tumor associated with Ollier disease	2. Sporadic
3. Teratoma, dysgerminomas	3. Male limited AD
4. Chorionepithelioma	4. Tuberous sclerosis
5. Sex-cord tumor with annular tubules (SCTAT) associated with Peutz-Jeghers	5. Leydig cell tumor
6. Autonomous functional cyst of the ovary	6. Congenital adrenal hyperplasia
7. McCune-Albright syndrome	7. Adrenocortical tumor
8. Simple follicular cysts	8. Teratoma
9. Feminizing adrenocortical tumor	9. Exogenous androgens
10. Exogenous steroids	
Heterosexual (Virilization)	Heterosexual (Feminization)
1. Congenital adrenal hyperplasia	1. Adrenocortical tumor
2. Adrenocortical (testosterone secreting) tumor	2. Exogenous estrogen
3. Androblastoma (arrhenoblastoma)	3. Sertoli cell tumor
4. Teratoma (androgen producing)	4. Sex-cord tumor with annular tubules (SCTAT)
5. Exogenous androgens	associated with Peutz-Jeghers

1. Absence of spontaneous gonadotropin pulsatile activity.
2. Weak but variable response to GnRH test.
3. No clinical response to GnRH analog therapy.
4. Cyclical steroidogenesis.

Occasionally, in longstanding and untreated cases, the elevated sex steroids due to adrenal or ovarian pathology may stimulate early maturation of hypothalamic-pituitary axis resulting in GnRH dependent precocious puberty.

Etiology

Central precocious puberty represents four-fifths of the total number of patients with precocious puberty and is much more frequently seen in girls than in boys, the ratio being 10:1 in favor of girls. Central precocious puberty in girls, i.e. activation of the hypothalamus-pituitary-ovary axis, accounts for more than 90 percent of precocious puberty cases in published series. Idiopathic central precocious puberty is diagnosed when early pubertal development (including acceleration of growth and bone maturation) is associated with a pubertal pattern of gonadotropin secretion (increased LH secretion) and when there is no evidence of organic cause provided through history, physical examination, or brain imaging.

Among patients with central precocious puberty, the proportion of idiopathic forms varies between 58 and 96 percent. This proportion is greater in girls than in boys (nearly 80 percent of CPP in girls). Boys show a higher prevalence of recognizable organic forms. With more frequent use of MRI in the work-up of girls with idiopathic central precocious puberty, benign hypothalamic hamartomas are increasingly reported. This difference in sex in the incidence of idiopathic CPP may indicate a lower gonadotrophin threshold to endogenous pulsatile GnRH in girls. In girls, it is now recommended that investigations like ultrasound of the ovaries and a low dose (0.25 mcg/kg IV) GnRH test be undertaken to confirm the mechanism of CPP and to exclude an underlying cause. While neuroradiological investigation is compulsory in boys with CPP, it may be carefully considered in girls with CPP. Gonadotrophin stimulation in boys is indicated by a testicular size of more than 2.5 cm or a testicular volume of more than 4 ml. These boys must be evaluated radiologically and endocrinologically (early morning testosterone, hCG and GnRH test) for organic causes based on history and physical examination. The causes of CPP are indicated in Table 1.

In both types of sexual precocity there is increased height velocity, somatic development and sexual maturation due to increased gonadal sex steroids. The advanced bone development with initial tall stature results in premature epiphyseal fusion and final short stature. Left untreated, most boys will not grow taller than 155 cm (5 feet 2 inches), and girls often do not grow taller than 150 cm (5 feet).

Central Nervous System Disorders in CPP²¹⁻²⁷

Lesions of the CNS are well recognized as causing central precocious puberty. Common causes include static encephalopathy due to infection, hypoxia, trauma, or irradiation during infancy or early childhood.

Hypothalamic Hamartomas

A less common but important cause of central precocious puberty is a CNS tumor. Hypothalamic hamartomas are benign tumors that have been shown to contain measurable GnRH. They probably act as ectopic GnRH pulse generators that have escaped from the normal inhibitory influences exerted in the prepubertal period on the centers that normally secrete GnRH. These small tumors are more frequently diagnosed in boys than in girls and are most easily visualized using MRI, as some may only be 2 or 3 mm in size. These tumors tend to grow slowly, if at all, and uncommonly cause neurologic symptoms. Symptomatic hamartomas are associated with gelastic or laughing seizures. Precocious sexual development is adequately controlled with GnRH agonists in patients with hamartomas. Optic and hypothalamic gliomas, astrocytomas,

ependyomas, or craniopharyngiomas may also cause CPP by possibly impinging on the neural pathways that inhibit the GnRH pulse generator in childhood. Treatment for these tumors is surgical.

The chance of finding CNS pathology in either sex is inversely proportional to the age of the child, with the greatest yield in children younger than 4 years old. In girls whose pubertal development start began after 6 years of age, any CNS pathology will be already known or clinically evident, suggesting that routine MRI in these children will less likely have positive findings.²⁷ In contrast, Pescovitz and coworkers reported that in a series of 4000 children referred to the National Institutes of Health, about one third of the girls and over 90 percent of the boys had an identifiable lesion of the CNS visible on computed tomography or MRI scans.²⁸ This high prevalence of CNS lesions in their series reflects the referral population.

PRECOCIOUS PSEUDOPUBERTY

McCune-Albright Syndrome

(Precocious Puberty with Polyostotic Fibrous Dysplasia and Abnormal Pigmentation)

McCune-Albright syndrome refers to a syndrome of autonomous hyperfunction of single or multiple (pituitary, thyroid, and adrenal) endocrine organs associated with patchy cutaneous pigmentation and fibrous dysplasia of the bones. Sexual precocity in girls has been the commonly noted endocrinopathy. A missense somatic gene mutation encoding the α -subunit of GS, the G protein stimulates cyclic adenosine monophosphate (cAMP) formation, resulting in the formation of the putative gsp oncoprotein. Activation of receptors (e.g. corticotropin [ACTH], TSH, FSH, LH receptors) that operate with a cAMP-dependent mechanism, as well as cell proliferation, ensues. Because the mutation is somatic, rather than genomic, it is expressed differently in different glands or tissues; hence, the variability of clinical expression in different patients.

In girls, the most common presentation is precocious puberty, occurring even as early as 6 months with vaginal bleeding reported at 4 months of age and development of secondary sex characteristics. Estradiol levels vary from normal to markedly elevated; levels of LH and FSH are suppressed with no response to GnRH stimulation. The ovaries are often enlarged asymmetrically and there are multiple functional cysts. In boys, precocious puberty is less common. Unlike ovarian enlargement in girls, testicular enlargement in boys is fairly symmetric. It is followed by the appearance of phallic enlargement and pubic hair, as in normal puberty. Testicular histology has demonstrated large seminiferous tubules and no or minimal Leydig cell hyperplasia; these findings may simply reflect the fact that biopsy specimens were obtained at an early stage

of pubertal development. In girls and boys, when the bone age reaches the usual pubertal age range, gonadotropin secretion begins, and the response to GnRH becomes pubertal. True (gonadotropin-dependent) precocious puberty overrides the antecedent (gonadotropin-independent) precocious pseudopuberty. In girls, menses become more regular, but often not completely, and fertility has been documented.

Multinodular goitrous hyperthyroidism/ bilateral nodular adrenocortical hyperplasia with Cushing syndrome may antedate the sexual precocity. The ACTH levels are low, and adrenal function is not suppressed by large doses of dexamethasone. Bilateral adrenalectomy is the treatment in such instances. Increased secretion of growth hormone may cause gigantism or acromegaly or tall stature with increased rates of growth even in the absence of precocious puberty. Girls and boys are equally affected. Serum levels of prolactin are increased in most patients, but fewer than half of the patients have a demonstrable pituitary tumor.

Pubertal progression is variable in these patients. Functioning ovarian cysts often disappear spontaneously; aspiration or surgical excision of cysts is rarely indicated. For girls with persistent estradiol secretion, agents that interfere with the final step of estrogen biosynthesis, that is, aromatase inhibitors such as testolactone, letrozole or anastrozole, or antiestrogens (such as tamoxifen) may limit, to a variable extent, the estrogen effects on pubertal and osseous maturation. Associated therapy with long-acting analogs of GnRH is indicated only for patients whose puberty has shifted from a gonadotropin-independent to a predominantly gonadotropin-dependent mechanism. Octreotide, a long-acting somatostatin analog, has been used to treat the hypersomatotropism. The prognosis is favorable for longevity, but deformities, repeated fractures, pain, and occasional cranial nerve compression may result from the bony lesions.

Of the extraglandular manifestations, phosphaturia, leading to rickets or osteomalacia, is the most common. Cardiovascular and hepatic involvement (e.g. severe neonatal cholestasis) is rare but may be life-threatening.

Syndrome of Precocious Puberty and Hypothyroidism

Precocious puberty is described in children with long-standing, untreated hypothyroidism. Unlike other children with precocious puberty, the bone age is retarded. Other characteristic features of hypothyroidism are noted along with growth retardation and delayed bone age. Testicular enlargement with modest or no penile enlargement but no pubic hair development is seen in boys. Primarily breast enlargement and menstrual bleeding are the features of advanced sexual development in these girls with hypothyroidism. Large, multicystic ovaries are often

seen by pelvic sonography. Skull film or MRI may show enlargement of the sella. Marked elevation of plasma levels of thyroid-stimulating hormone (TSH) and mild elevation of prolactin are seen. Serum FSH and LH are low.

Precocious puberty associated with hypothyroidism behaves as an incomplete form of gonadotropin-dependent puberty. Highly elevated TSH probably interacts with the FSH receptor ("specificity spillover"), thus inducing FSH-like effects in the absence of LH effects on the gonads. Unlike in true precocious puberty, testicular enlargement occurs without substantial Leydig cell stimulation and testosterone secretion in affected boys. In affected girls, ovarian estrogen production occurs without a concomitant increase in androgens. Treatment of the hypothyroidism results in rapid return to normal of the biochemical and clinical manifestations. Macroorchidism is known to persist in adult life despite adequate thyroxine therapy.

ECTOPIC PRODUCTION OF HUMAN CHORIONIC GONADOTROPHINS

Gonadotropin-Secreting Tumors

Hepatic Tumor

Hepatoblastoma in boys may be associated with isosexual precocious puberty because of tumor cell synthesis and release of human Chorionic Gonadotropins (hCG), which stimulates the LH receptors in the Leydig cells of the testes. Whenever, in a case of isosexual precocious puberty, the physical examination reveals hepatomegaly, this diagnosis must be entertained. The children with early onset of puberty are usually in the age range of 3 to 8 years. Plasma levels of hCG and α -fetoprotein are usually markedly elevated; they serve as useful markers for following the effects of therapy. Plasma levels of testosterone are elevated, and the FSH and LH levels, as measured by specific, immunometric assays, are low. Plasma levels of hCG and α -fetoprotein are usually markedly elevated; they serve as useful markers for following the effects of therapy. Plasma levels of testosterone are elevated, and the FSH and LH levels, as measured by specific immunometric assays are low. Prognosis even after treatment of the tumor is poor.

Other Tumors

Choriocarcinomas, teratocarcinomas, or teratomas (also called ectopic pinealomas or atypical teratomas), located in the CNS, mediastinum, gonads, or even adrenal glands may elaborate chorionic gonadotropin, thereby causing precocious puberty. These are more common in boys than in girls. Affected patients often have marked elevations of hCG and α -fetoprotein. In boys with Klinefelter syndrome, strangely, mediastinal tumors and not gonadal tumors have been responsible for the appearance of precocious puberty.

Medicational Precocity

Premature appearance of secondary sexual characteristics may be caused by medicines, creams, ointments, cosmetics containing estrogens. Breast development in girls and gynecomastia in boys have occurred because of exposure to these agents. Precocious pseudopuberty has occurred in both boys and girls from the accidental ingestion of estrogens (including contraceptive pills) and from the administration of anabolic steroids. The use of estrogens in animal husbandry is believed to be responsible for the high prevalence of premature thelarche and precocious pseudopuberty in Puerto Rico. A careful history focused on exploring the possibility of accidental exposure to or ingestion of sex hormones is important. Exogenous estrogens may produce an intense, dark brown color in the areola of the breasts that is not usually seen in endogenous types of precocity. The precocious changes disappear after cessation of exposure to the hormones.

Incomplete, Unsustained, and Intermittent Forms of Sexual Precocity (Variations of Normal Puberty—Early)

Premature Thelarche

Limited breast development developing prematurely in young girls, sometimes as young as eighteen months of age, without further progression to a mature breast and without any other signs of puberty is termed premature thelarche. The growth rate is normal as in other prepubertal girls, with a bone age appropriate for chronologic age. Levels of gonadotropins and estradiol are normal, and ultrasound images of the ovaries are unremarkable. This benign condition usually resolves spontaneously and requires no treatment. A biopsy of the breast tissue, being an anatomic equivalent of a partial mastectomy, is not warranted as it alters the subsequent breast development.

Some children who present with breast development later than 2 years are more likely to have some degree of continued breast development, representing an early stage of precocious puberty. Once breast development is stimulated much beyond the breast-bud stage and reaches early adolescent proportions, breast contour generally does not regress. Approximately 10 to 15 percent of these girls develop CPP, but in the majority of patients the breast bud is a transient event that warrants only close follow-up for the appearance of other pubertal signs.

Premature Pubarche

Precocious pubarche is most often a benign condition secondary to early adrenarche. Mild errors of steroidogenesis have been reported with ACTH stimulation tests in 12 percent of children with precocious pubarche. In the majority of those basal 17-OH progesterone levels were higher than in pubertal norms and were felt to be

a good screening test to determine which patients should undergo ACTH stimulation testing. In some patients premature pubarche may predict the future development of chronic anovulation and androgen excess associated with polycystic ovarian syndrome.

Symptoms, Signs, and Diagnosis of Precocious Puberty

In both true precocious and pseudoprecocious puberty, boys may exhibit facial, axillary, and pubic hair; penile growth and increased masculinity. Girls develop breasts and pubic and axillary hair. Girls begin to menstruate more commonly with true precocious puberty, but menstruation may also occur with pseudoprecocious puberty (such as in McCune-Albright syndrome). Body odor and acne, as well as behavior changes, may be present in both sexes. Linear growth is initially rapid in both sexes, but the adult height is shortened by premature closure of the epiphyses. Testicular or ovarian enlargement, which occurs in true precocious puberty, is usually absent in pseudoprecocious puberty. However, ovarian cysts may occur in some cases of McCune-Albright syndrome or in association with sporadic menstruation.

Evaluation of Children with Precocious Puberty (Flow charts 1 and 2)

The evaluation starts with history and physical examination and they contribute immensely to the diagnostic possibility and give a lead to the type of laboratory evaluation. A detailed medical history is essential and must be obtained with special focus on the occurrence of prior CNS injury at birth or later, infections, radiation, seizure activity, headache, visual disturbance, and polydipsia, exposure to exogenous sex steroids in cosmetics or food, or a positive family history – age of puberty and the height of parents and siblings and occurrence of PP in other family members.

The clinical examination must be carried out in the presence of a chaperone and will pay attention to record

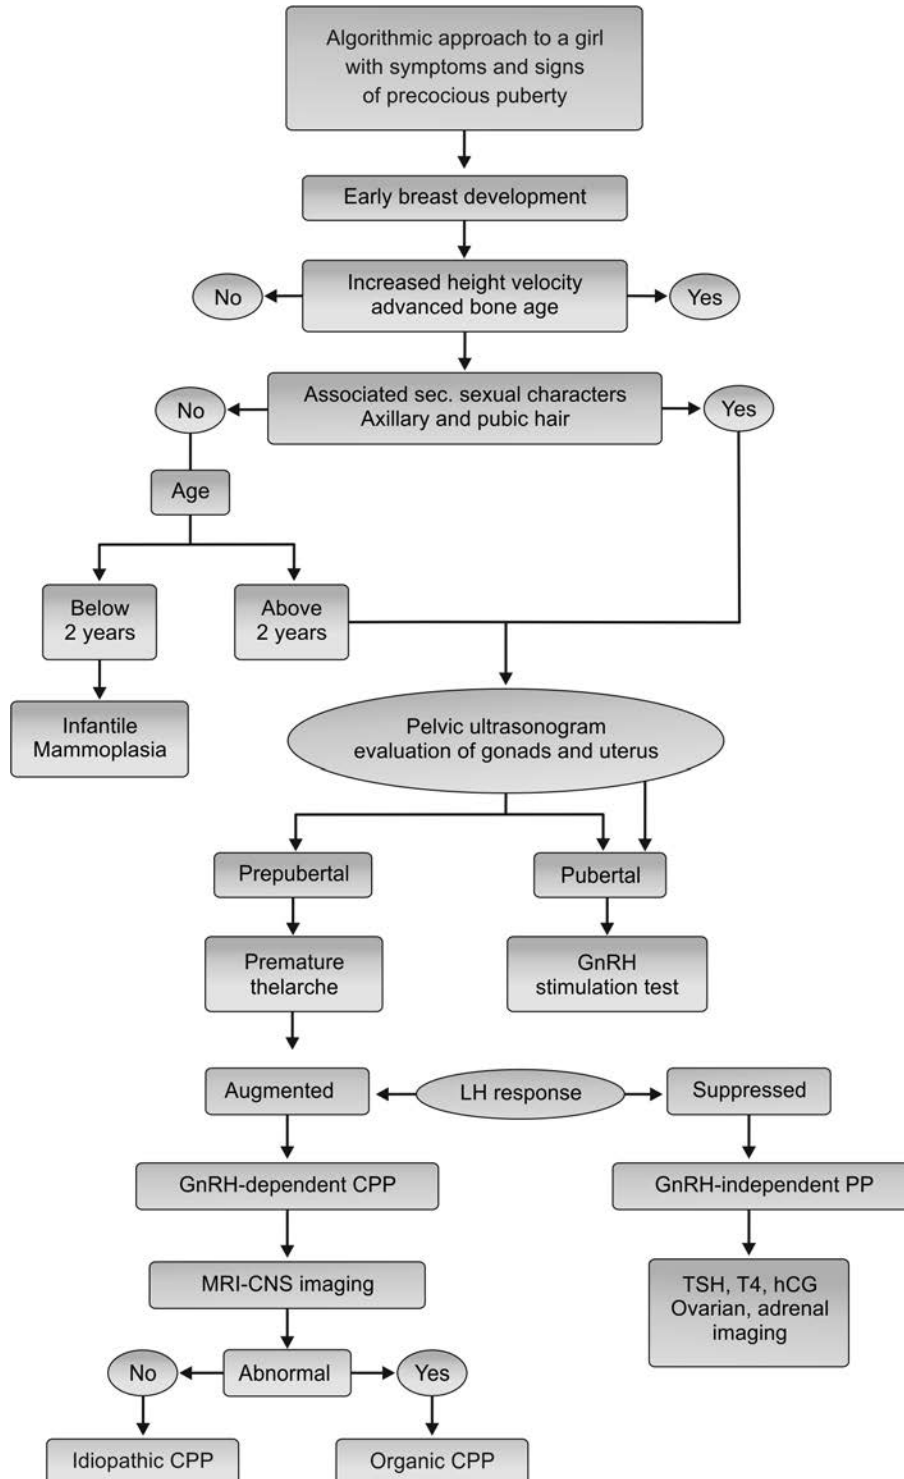

- The presence of various signs of pubertal development - acne, comedones, skin oiliness, facial hair, axillary hair and odor, voice change and muscular development.
- The stage of advancement of gonadal and pubic hair development with attention to details like size, shape and volume of the testes and penile length in boys and the stage of breast and pubic hair development in girls.

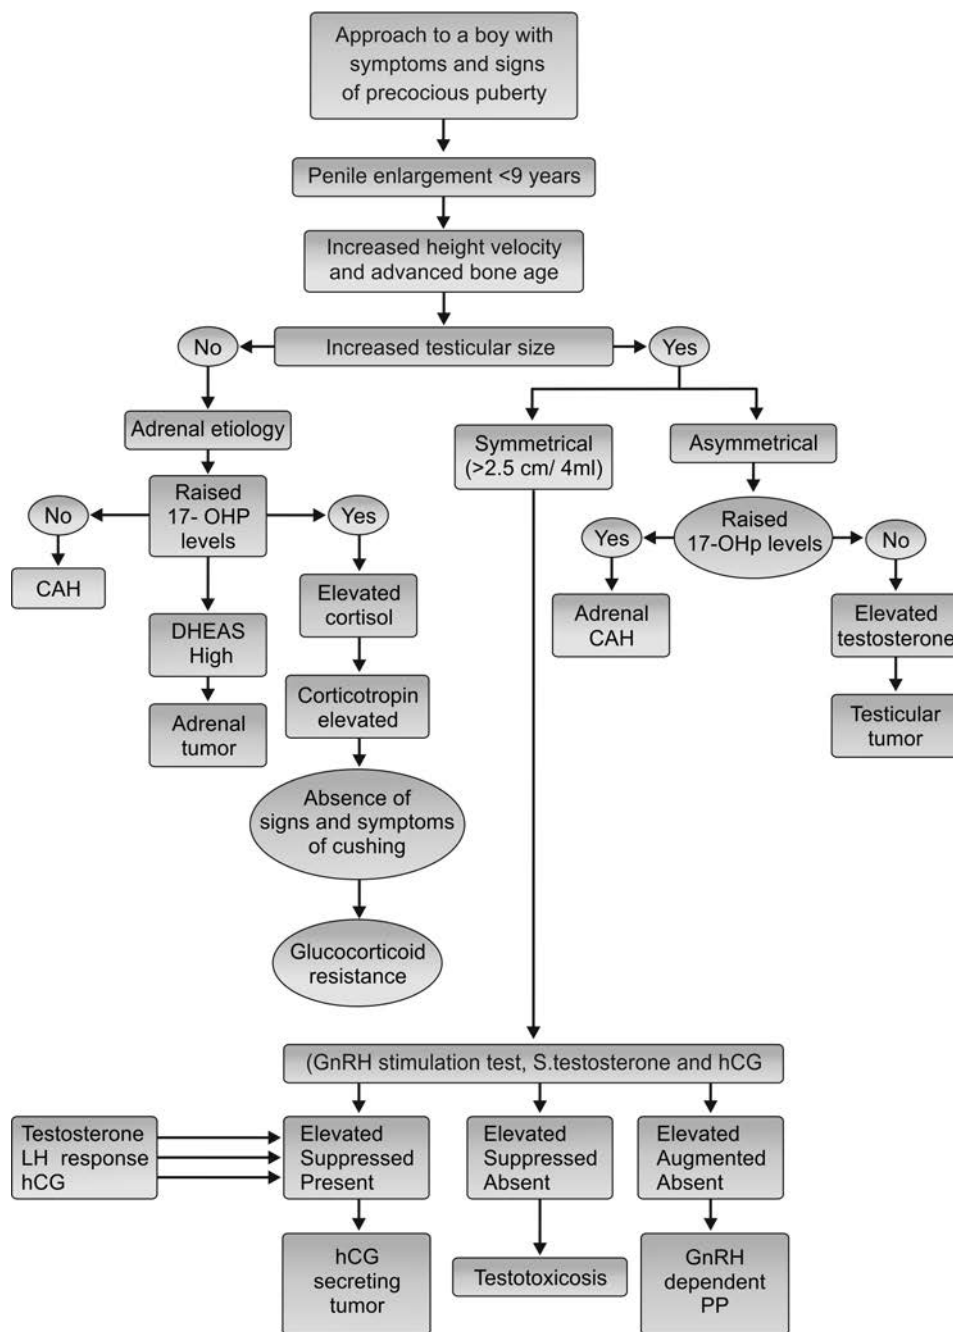

In girls, physical examination should focus on determining whether the development reflects androgen action, estrogen action, or both. In boys with true precocious puberty, the testes will start enlarging symmetrically, whereas in boys with Leydig cell tumors or adrenal rests, the testes show asymmetrical, nodular enlargement.

Examination of the skin may identify presence of café au lait spots of neurofibromatosis or McCune-Albright syndrome, neurofibromas, dry and thick skin of hypothyroidism. A detailed neurological examination must evaluate

the optic disks, visual fields and identify signs of increased intracranial pressure. Acanthosis nigricans has been noted with significant endocrinal conditions in 58 percent (15 of 26) of 6 to 8 year girls referred for early puberty.

Flow chart 1: Approach to a girl with early development of breast and/or other secondary sexual characters

Flow chart 2: Approach to a boy with early development of penile enlargement

Examination of the skin may identify presence of café au lait spots of neurofibromatosis or McCune-Albright syndrome, neurofibromas, dry and thick skin of hypothyroidism. A detailed neurological examination must evaluate the optic disks, visual fields and identify signs of increased intracranial pressure. Acanthosis nigricans has been noted with significant endocrinal conditions in 58 percent (15 of 26) of 6 to 8 year girls referred for early puberty.

Diagnostic Evaluation (Tables 3 to 5)

Radiological Evaluation

Radiological assessment of bone age (hand and wrist X-ray) as a marker for sex steroid hormone is an essential step to determine the need for specific therapy. In general when skeletal age is concordant with chronological age continued close observation may be elected. An advanced bone age by 2 years or more associated with secondary sexual

Table 3: *Evaluation of precocious puberty*

Common initial screening tests

- Careful history, physical examination, and assessment of growth velocity
- Bone age
- LH, FSH
- Estradiol, testosterone
- DHEA-S
- 17-hydroxyprogesterone
- TSH, T4

Secondary tests to consider

- Pelvic ultrasound
- MRI of head
- β -hCG
- GnRH or leuprolide stimulation test
- ACTH stimulation test

characteristics indicate the likely duration of the presence of precocious puberty for a year or more or the rapidity of advancement of puberty. This warrants estimation of levels of estradiol, testosterone, and thyroid hormone. Advanced bone age by only one year needs observation for early development of pubertal features. Skull lateral radiographs may rarely show widening of pituitary fossa or craniopharyngiomas; they are not useful in indicating the presence and type of intracranial tumors or lesions that are often responsible for the development of precocious puberty.

Pelvic ultrasound is an essential investigation for precocious pseudopuberty. Pelvic ultrasound examinations must be performed by competent radiographers trained in pediatric pelvic ultrasound assessments by the full bladder technique obtained by voluntary urine retention following oral administration of fluids. The criteria for assigning appearances as pubertal as opposed to prepubertal were dependent on the appearance of the uterus, including the presence or absence of an endometrial echo. In girls with a definitive diagnosis of Central Precocious Puberty It does not give additional information, except that it may show bilaterally enlarged ovaries, often with multiple small follicular cysts, and an enlarged uterus with an endometrial stripe. Abdominal ultrasound may reveal the presence of gonadal or adrenal tumors or cysts.

Neuroimaging Studies²³⁻²⁶

In most cases, the diagnosis of gonadotropin-dependent precocious puberty (CPP) based on prior endocrinological evaluation warrants a high resolution MRI or

Table 4: *Serum testosterone levels*

Stage	Levels
Generally prepubertal *	<30 ng/dl
Early pubertal	30-100 ng/dl
Midlate pubertal	100-300 ng/dl
Adult	>300 ng/dl

* Depending on the laboratory, testosterone levels of 11-30 ng/dL may represent early puberty.

computerized tomography (CT) head scan with special attention to hypothalamic-pituitary region. The younger the child with CPP (children below 6 years of age), the greater the chance of finding a CNS lesion. Magnetic resonance imaging is now recognized as superior to CT in neuroimaging. For boys, the incidence of CNS findings is much higher than in girls, and MRI should be part of the routine evaluation. Increasing use of MRI in girls with central precocious puberty has been shown to increase the detection rate of abnormalities in the hypothalamo-pituitary region which might have been missed by previous techniques and hence a few investigators feel that neuroimaging with MRI must be routinely included in the work up of girls with CPP.²⁴⁻²⁶

Histopathology

Histopathology of the brain tumor in the hypothalamic-pituitary area is important in prognostication and treatment plan. Gliomas tend to grow more rapidly than astrocytomas, while hamartomas generally are benign.

Endocrinological Evaluation

The endocrinological evaluation includes determination of serum concentrations of gonadotrophins, testosterone and possibly dehydroepiandrosterone (DHEAS) and estradiol measurements

Gonadotropins

Random LH and FSH levels have limited value in the work-up for possible precocious puberty, since standard radioimmunoassays provide ample overlap between levels seen in prepubertal and early pubertal subjects. If random LH and FSH levels exceed 5 IU/L, a diagnosis of precocious puberty is almost certain. Suppressed levels (i.e. <0.1 IU/L) of LH and FSH accompanied by highly elevated testosterone or estradiol levels point to precocious pseudopuberty rather than CPP. The use of newer, more ultrasensitive assays such as chemiluminescence assays for LH and FSH now appear to have greater accuracy for distinguishing levels in prepubertal versus pubertal children and is proposed to indicate the onset of gonadarche even in the absence of a dynamic GnRH test.

Table 5: *Evaluation and diagnosis of central true precocious puberty*

Clinical condition	True precocious puberty (pituitary gonadotrophin dependent states)			
Gonad size	Pubertal - testicular enlargement or ovarian and uterine enlargement			
Plasma gonadotropin levels - assay by 3rd generation	Prominent LH pulses, initially during sleep			
GnRH test - LH response	Pubertal			
Serum sex steroid levels	Pubertal levels of testosterone or estradiol			
Others – clinical and imaging	Skin and skeletal examination and survey: McCune-Albright syndrome Brain MRI/ CT: for CNS/ Hypothalamic tumors or other disorders			
Clinical condition	Chorionic GT secreting tumors	Virilizing CAH (Untreated)	Virilizing adrenal tumor	Leydig cell tumor
Gonad size	Symmetrical, >2.5 cm; but smaller in relation to pubertal development	Prepubertal testes; but enlarged phallus and advanced pubic hair development		Irregular, asymmetrical enlargement
Plasma gonadotropin levels - assay by 3rd generation	High hCG or + pregnancy test	Prepubertal		Suppressed
GnRH Test - LH response		Absent or prepubertal	Suppressed	Absent
Serum sex steroid levels	Pubertal	Raised androgens relating to the enzyme deficiency	High DHEAS, Androstenedione and testosterone	Very high testosterone levels
Others – clinical and imaging	Hepatomegaly in hepatoblastoma; radio-imaging US, CT. The MRI in CNS tumors secreting hCG	After initiation of glucocorticoids, development of complete PP needs therapy	US abdomen; CT and MRI; selective venous sampling	
Clinical condition	Familial Leydig and germ cell maturation		McCune-Albright Syndrome	Premature adrenarche
Gonad size	Symmetrical, >2.5 cm; smaller in relation to pubertal development; spermatogenesis +/-	Symmetrical, > 2.5 cm; smaller in relation to pubertal development	Prepubertal	
Plasma gonadotropin levels - assay by 3rd generation	Suppressed	Prepubertal at first stage	Prepubertal	
GnRH test- LH response	Absent	Absent		
Serum sex steroid levels		Pubertal levels of testosterone	Prepubertal testosterone; DHEAS : pubic hair stage 2	
Others – clinical and imaging	Familial; sex-limited AD trait	Café au lait spots; polyostotic fibrous dysplasia; other hyperendocrinopathies - thyrotoxicosis, gigantism, etc.	Usual onset: Beyond 6 years of age	

GnRH Test

This test is indicated in the diagnosis of central precocious puberty (CPP) in suspected children. A pubertal response of LH will differentiate CPP from other peripheral causes. The determination of gonadotrophins LH and FSH in a single blood sample drawn after GnRH administration has simplified the diagnostic work-up of CPP. A definitive central precocious puberty (CPP) diagnosis is confirmed by a brisk rise in LH 20 to 40 minutes after infusion of 100 mcg of GnRH, which is more than the rise in FSH. No increase in LH and FSH after infusing GnRH suggests precocious pseudopuberty. Prepubertal girls with premature thelarche sometimes show an exaggerated rise in FSH after GnRH. A FSH rise more than the LH rise does not indicate CPP.

Sex Steroid Levels

For girls, because of weekly fluctuations of levels, estradiol measurements are less reliable indicators of the stage of puberty. Though levels exceeding 20 pg/ml usually indicate puberty, some girls who are definitely pubertal may have levels less than 20 pg/ml. Girls who have ovarian tumors or cysts often have estradiol levels that exceed 100 pg/ml.

Serum testosterone evaluation is useful for boys with suspected precocious puberty. Table 4 outlines the approximate correlation of this test with the stage of puberty. Note that because LH and testosterone rise with sleep onset in early puberty, early morning testosterone is higher than afternoon levels.

Adrenal androgen levels are helpful in the evaluation of PPP only when an adrenal tumor is considered to be present because of rapid virilization as it is generally associated with extremely elevated DHEA and DHEAS. Levels of adrenal androgens (e.g. dehydroepiandrosterone [DHEA], dehydroepiandrosterone sulfate [DHEAS]) are elevated modestly in boys and girls with early growth of pubic hair. If congenital adrenal hyperplasia is suspected, serum levels of 17-OH progesterone are estimated. For greatest accuracy of diagnosis, an adrenocorticotrophic hormone (ACTH) stimulation test gives the greatest diagnostic accuracy. A high-normal random 17-OH progesterone finding with an elevated level 30 to 60 minutes after ACTH injection may be seen.

Thyroid hormonal tests are not a routine requirement. Severe hypothyroidism rarely leads to precocious puberty. Major clues of severe hypothyroidism are growth arrest instead of growth acceleration, galactorrhea, and signs of thyroid hormone deficiency. In primary hypothyroidism, mild testicular enlargement is likely because of raised FSH; Free T4 will be low and TSH is elevated; LH levels will be prepubertal.

Treatment

Treating early puberty is important for physical as well as emotional and social reasons. Children with precocious

puberty may initially appear taller than their peers, but they stop growing too soon and end up at a shorter height than normal. If untreated, boys typically grow no taller than 160 cm (5 feet 4 inches) and girls rarely reach 150 cm (5 feet). Hence, the main goals of therapy in PP are to preserve adult height and alleviate potential psychosocial effects of precocious puberty.

Objectives of treatment in precocious puberty	Determinants for initiation of specific treatment in precocious puberty
To arrest and cause regression of existing secondary sexual characteristics	Age, overall health status and medical history of the child
To arrest premature sexual maturation until normal age of puberty	Time of onset, extent and degree of advancement of the condition
To halt the rapid rate of skeletal maturation and to prevent early epiphyseal fusion, so as to prevent final short stature and attain near normal mature height	Expectations for the course of the condition
To alleviate the emotional and psychosocial problems identified in the child	Affordability (cost), availability and accessibility (local) and acceptability
To detect and treat the primary etiological condition	Tolerance of the child for specific drugs and therapies
To counsel and relieve the parental anxiety	Pediatrician's or endocrinologist's preference based on evidence, experience, familiarity and recent advances

Treatment of Central Precocious Puberty

Gonadotropin Releasing Hormone Agonist

GnRH agonists remain the mainstay of treatment for centrally mediated gonadotropin dependent precocious puberty. These potent long-acting synthetic analogs of natural GnRH, suppress pituitary gonadotropin secretion by providing continuous stimulation, whereas the pulsatile stimulation of endogenous GnRH is the cause for pubertal progression. This downregulation of the pituitary–gonadal axis by the administration of these GRnH analogs limits pubertal progression and arrests and/or regresses physical pubertal development thereby slowing the accelerated pubertal growth rate and bone maturation.²⁸⁻³² The rate of growth and bone maturation during treatment slows, but this rate depends upon the advancement of bone age and skeletal maturation at the time of initiating the therapy. Adult height potential can be preserved by GnRH analog therapy, if treatment is started early enough. Height lost however cannot be regained and so early, prompt treatment is considered essential. Various formulations (intramuscular, subcutaneous, and intranasal) of short- (daily)

and long- (monthly) acting GnRH agonists are available, with depot leuprolide being the most commonly used preparation in the United States. Newly developed 3-month depot formulations also have been shown to be effective.

Gonadotropin-releasing hormone agonists have been shown to improve adult height compared with pretreatment predicted height in children with CPP,^{32,33} but outcomes are variable with children younger than 6 at initiation of therapy gaining the most height and those over 8 showing little benefit. GnRH agonists generally are tolerated well, but occasionally, an initial, temporary flare of GnRH activity can occur and result in transient advancement of secondary sexual characteristics and even vaginal bleeding. Initial concerns about long-term effects of GnRH agonists on bone mineral density have been alleviated,³⁴ GnRH agonist therapy does not lead to obesity, a serious reported and voiced concern.^{35,36}

Leuprolide (leuporelin), triptorelin, goserelin, histrelin acetate and deslorelin are available for subcutaneous and depot intramuscular injection, nafarelin and buserelin are available for subcutaneous and nasal applications.

Drug	Leuporelin	Triptorelin	Goserelin
Preparation	Microsphere suspension	Microsphere suspension	Implant
Injection site and route	Abdomen-SC; Buttocks, thigh - IM	Abdomen-SC; Buttocks, thigh - IM	Abdomen, buttock-SC
3-4 weekly Prep.	Yes	Yes	Yes
10-12 weekly Prep.	Yes	No	Yes

Depot Formulations of Long-acting GnRH Analogs

These maintain fairly constant serum concentration of the drug for weeks, constitute the preparations of choice for treatment of central precocious puberty. Leuprolide acetate, a depot preparation is given in a dose of 0.25 to 0.30 mg/kg/month (minimum, 7.50 mg) intramuscularly. In five percent of children with local reactions like sterile fluid collection at the site of injection, treatment should be changed to subcutaneous injections of aqueous leuprolide, given once or twice daily (20-50 mcg/kg/mo; total dose 600 µg/kg/24 hr), or intranasal administration of the GnRH agonist nafarelin 400 µg to 800 µg bid. The dose of triptorelin is 60 mcg/kg/month. Goserelin acetate is approved for treatment of precocious puberty in other countries. A 12-month implant (histrelin) is also available for use in USA.

Treatment is usually started with a monthly depot preparation given by SC or IM injection. Cyproterone acetate is given initially for a few weeks to counter the effects of the initial 'flare' in gonadotrophin secretion. The acute

GnRH stimulation test is repeated after a few months to determine whether LH and FSH levels are suppressed. Later, it may be possible to maintain adequate gonadotrophin suppression using a 3-monthly long-acting preparation. The duration of therapy is individualized according to age of child, maturity of child, predicted adult height. Usually the treatment is continued until 10 years of age. A withdrawal bleed may occur in some girls following the first GnRH a injection.

GnRH Antagonists

The GnRH antagonists have only recently become commercially available and are currently under study for treatment of sexual precocity. The GnRH antagonist act by competitive binding to GnRH receptors and suppresses pituitary gonadotrophin secretion without any initial outbursts.

Monitoring the Response and Follow-up

The follow-up should be done every 3 to 4 months to ensure that progression puberty has been arrested. Height and height velocity should be monitored. A decrease in testicular size and serum testosterone are sufficient indicators of efficacy of treatment in boys. In girls, a GnRH test should be done initially at 3 to 4 months and then it can be done on yearly basis.

Other Treatment Options

Historically, medroxyprogesterone and cyproterone acetate were used in an attempt to suppress activation of the hypothalamic-pituitary-gonadal axis. In addition, cyproterone acetate has antiandrogenic effect. Neither of these agents was satisfactory as they were not fully effective in inhibiting pubertal or skeletal maturation or improving adult height.

1. Medroxyprogesterone acetate.
2. Cyproterone acetate.

Treatment of Peripheral Precocious Puberty

Treatment of peripheral precocious puberty involves treating the underlying disorder and limiting the effects of elevated sex steroids. Testotoxicosis is often treated with ketoconazole, which is a nonspecific inhibitor of steroidogenesis. Alternative therapies include spironolactone (androgen receptor inhibitor)/flutamide with letrozole, medroxyprogesterone acetate, testolactone and anastrozole (aromatase inhibitor), and tamoxifen (estrogen receptor inhibitor). Recently, tamoxifen has shown particular promise for treatment of McCune-Albright syndrome, but long-term efficacy and safety data are needed.³⁷

McCune-Albright syndrome with multicystic ovaries, elevated estradiol, low basal LH and prepubertal response to GnRH stimulation is treated with tamoxifen, testolactone/aromatase inhibitor.

Surgery of Adrenal or Gonadal Tumors

In most cases, hormone-producing tumors, specifically granulosa cell tumors in girls, should be excised. However, prolonged follow-up is necessary in case of recurrence in the contralateral ovary. Excision is also an option for the various neoplasms causing pseudopuberty in males. However, some of these tumors are aggressively malignant and associated with high mortality.

Testicular/Ovarian/Adrenal Tumors

These tumors are mostly unilateral and should be removed surgically, once removed the remaining contralateral testis, ovary and adrenal glands should recover from suppression and be adequate for normal function.

Congenital Adrenal Hyperplasia

The classic and simple virilizing CAH requires lifelong therapy with glucocorticoids and mineralocorticoids in both males and females.

Psychological Counseling and Emotional Support

Indication for such a treatment on the basis of psychologic and behavioral anomalies has to be determined on an individual basis. Parents who are anxious and worried must be counseled and the evaluation and treatment plan must be discussed with them.

Prognosis of CPP with GnRH Analog Treatment

The adult heights attained by untreated children with CPP often are below the fifth percentile. The cause of the precocious puberty, as well as the age at onset, rapidity of progression through puberty, and age when therapy is initiated, affects the height outcome. Several long-term studies of the treatment of CPP with GnRHa, now indicate that treatment results in improved adult height in most patients. Though some patients attain adult heights that surpass their target heights, a substantial number of treated children with GnRH analogs do not attain their targeted adult heights. Deceleration in growth is expected during GnRHa therapy, but in some patients the decrease during therapy is so great that the expected improvement in predicted adult height is not achieved. Even after several years of therapy, they attain adult heights that are significantly less than their target heights.

SUMMARY

Precocious puberty is not uncommon in pediatric practice. The definition of precocious puberty in girls, i.e. the cut-off age before which there is appearance of secondary sex characters has been modified in the USA, because of advancement of menarche in American black and white girls. The clinical and investigative approach towards this endocrinal problem differs in boys and girls with early development of pubertal features. Advanced bone age results in earlier

epiphyseal fusion causing ultimate short stature. After ruling out the normal variant precocious thelarche and pubarche, the clinician must refer the child to competent experts to have proper investigational work-up and treatment, so that their pubertal features can regress and the final adult height does not get reduced. There are contradicting recommendations regarding the routine need for neuroimaging of girls with central precocious puberty, because majority of them has no identifiable lesion and hence considered idiopathic. Boys with CPP must have total work-up as they have a definite, identifiable cause. The GnRH analogs have become the drug of choice to treat CPP. The peripheral precocious puberty, with its identifiable cause, must be treated accordingly. These children and parents need appropriate counseling and psychological support. These children also need regular follow-up—monitoring of height, bone age, regression of pubertal features and psychosocial adjustment till they attain their regular age of puberty.

Metabolic Syndrome in Children and Adolescents

Archana D Arya

The *Metabolic Syndrome* also known as syndrome X is characterized by:

- *Obesity* (abdominal)
- *Atherogenic dyslipidemia* (elevated triglyceride [TG] levels, high low-density lipoprotein [LDL] particles, and low high-density lipoprotein cholesterol [HDL-C] levels)
- *Raised blood pressure*
- *Insulin resistance* (with or without glucose intolerance),
- *Prothrombotic inflammatory vascular environment*.

Obesity plays a central role in the development of the metabolic syndrome. As childhood obesity has increased, the complications associated with it have become more common. Doctors are witnessing the first consequences of this epidemic in the form of increased incidence of Type 2 Diabetes Mellitus (T2DM) among adolescents, hepatic steatosis, orthopedic problems, sleep apnea and others.^{1,2}

Diseases such as diabetes mellitus, systemic arterial hypertension and dyslipidemia, increase the risk of cardiovascular events. The association between obesity and coronary disease is already well established in adults.³

This association led to the term “metabolic syndrome” being created to define the condition of those people who are at greatest risk of cardiovascular events.⁴ The fact that the metabolic syndrome is being identified in children suggests that the development of cardiovascular disease will also occur earlier, increasing the risk of early death, therefore, raising a great health concern. Early identification of the metabolic syndrome may help target interventions to improve future cardiovascular health. Unless action is taken, diabetes experts agree that this is the first generation where children may die before their parents.

Recent studies suggest that the metabolic syndrome may originate *in utero*.

Intrauterine events for the unborn child and factors during early development years predispose a child to disorders such as obesity, prediabetes, and metabolic syndrome.

The presence of maternal gestational diabetes,⁵ low birth weight,⁶ and infant feeding practices⁷ for example contribute to a child's future level of risk. Other factors can be genetic, socioeconomic or environmental (an obesogenic environment for example).⁸

DEFINITION

There is no formal definition of metabolic syndrome in children and adolescents. Adaptation of the criteria used for adults is complicated because of the multiple definitions proposed by different organizations and because normal ranges for each criterion must be adjusted for each age group. However, the rapid rise in obesity trends underlines the urgency for a definition that could be used to further understand who is at high-risk of health complications and to distinguish them from those with “simple” uncomplicated obesity.

The wide variety of cut-off points used highlighted the need for a single definition that would use a consistent set of criteria, which would be easily measurable, with age-specific and sex-specific cut-off points.

Third Report of the Adult Treatment Panel (ATP III) defined metabolic syndrome (Met S) by using criteria easily applied by clinicians and researchers⁹ in 2001.

The Third National Health and Nutritional Survey (NHANES) carried out in children from 1988 to 1994, defined pediatric Met S using criteria analogous to ATP III as 3 or greater than 3 of the following criteria¹⁰ (Table 1).

Goodman et al. proposed a definition with BMI as a base, justifying that it would be less dependent on ethnic variations - we are aware that abdominal circumference may vary according to the race. The prevalence in moderately obese patients (considering those who had Z of 2 and 2.5) was 38.7 percent, and in severe obese patients (with Z over 2.5 of pattern deviations), it was 49.7 percent.¹¹

Table 1: Criteria for metabolic syndrome

<i>Fasting Triglycerides</i>	<i>HDL cholesterol</i>	<i>Fasting glucose</i>	<i>Waist circumference</i>	<i>Systolic blood pressure</i>
≥ 100 mg/dl	≤ 50 mg/dl Boys 15-19 years: <45 mg/dl	≥ 100 mg/dl	>75th % ile for age and gender	>90th % ile for gender, age and height

Table 2: The IDF consensus definition of metabolic syndrome in children and adolescents

<i>Age group (years)</i>	<i>Obesity (WC)</i>	<i>Triglycerides</i>	<i>HDL-C</i>	<i>Blood pressure</i>	<i>Glucose (mmol/L) or known T2DM</i>
6-<10	≥90th percentile	MS cannot be diagnosed, but further measurements should be made if there is a family history of MS, T2DM, dyslipidemia, CV disease, HT and/or obesity			
10-<16	≥90th percentile or adult cut-off if lower	≥150 mg/dl (≥1.7 mmol/L)	≤40 mg/dl (≤1.03 mmol/L)	Systolic≥130/ diastolic≥85 mm Hg	100 mg/dl If ≥ 100 mg/dl or known T2DM, recommend an OGTT
16+ MS	Use existing IDF criteria for adults i.e. Central obesity(WC≥94 cm and 80 cm for Europid men and women respectively, with ethnicity specific values for other groups) Plus any 2 of the following 4 factors: –raised triglycerides: ≥150 mg/dl –reduced HDL cholesterol: <40 mg/dl in males and <50 mg/dl in females, or specific treatment for these lipid abnormalities –raised BP: systolic=130 or diastolic=85 mm Hg or treatment of previously diagnosed hypertension –impaired fasting glycemia: FPG ≥100 mg/dl, or previously diagnosed type 2 diabetes				

MS: metabolic syndrome; WC: waist circumference; HDL-C: high-density lipoprotein cholesterol; T2DM: type 2 diabetes mellitus; OGTT: oral glucose tolerance test.

BMI is the most practical method for assessing obesity in children in a clinical practice. The WHO has recommended using BMI as an index of being overweight or obese.

Obesity is defined as a BMI > 95th percentile for age and sex. Those between the 85th and the 95th percentile are considered to be at risk for obesity. There are percentile charts available for BMI, related to age and sex, from NCHS that have been accepted widely. (<http://www.cdc.gov>)

In studies of lean and obese adolescents, it has been shown that the BMI correlates strongly with the visceral lipid depot. The BMI also correlates with blood pressure and dyslipidemia better than the waist circumference and hence may be a better indicator for obesity in children than waist circumference.

On the other hand the new IDF definition of metabolic syndrome in children and adolescents (Table 2) is inspired, in part, by the IDF worldwide definition of metabolic syndrome in adults.¹² The IDF definition has taken waist circumference (WC) as criteria for metabolic syndrome instead of BMI, similar to the adult criteria, because it is an independent predictor of insulin resistance, lipid levels, and blood pressure.¹³⁻¹⁷ Moreover, in young people who are obese and have similar body mass index (BMI), insulin sensitivity is lower in those with high

amounts of visceral adipose tissue and high waist/hip ratio than in those with low amounts.¹⁸⁻¹⁹

Although there has not been universal agreement as to which level to use for the criteria for the metabolic syndrome, several studies,^{12,20,21} have used the 90th percentile as a cut-off for waist circumference. Children with a WC higher than the 90th percentile are more likely to have multiple cardiovascular disease risk factors than are those with a waist circumference below this level.²²⁻²⁴ IDF has chosen to use the 90th percentile as a cut-off for WC, which will be reassessed when more outcome data become available.

Waist circumference in children is a good predictor of visceral adiposity,²⁵ but since body proportions normally change during pubertal development and may vary among persons of different races and ethnic groups.²⁶

Kuriyan et al. developed waist circumference percentiles based on a study on 9060 urban children (5172 boys and 3888 girls) in the age group of 3 to 16 years in Bangaluru in 2010. The waist circumference of the Indian children from the present study was higher than age and sex matched European children.

These curves represent the first waist and waist height ratio percentiles for Indian children but do not have national geographical representation.²⁷

The author suggested that for a start, the 75th percentile of waist circumference from this study be used as an “action point” for Indian children to identify obesity.

Virani studied 320 affluent children longitudinally from 5 major geographical regions in India for their waist circumference and developed WC percentiles.²⁸

Pandey et al published WC percentiles for Indian children from 14 to 18 years of age.²⁹

The WC percentiles of Indian children published recently have their limitations in terms of national representation and age groups. Method of measuring WC can also vary and most pediatricians are more comfortable with BMI as a parameter rather than measuring WC, hence it is suggested that pediatricians can continue to use BMI cut-offs at present for defining Met S.

Prevalence of Metabolic Syndrome in Adolescents

The NHANES III survey (1988-1994) revealed that the prevalence of metabolic syndrome was 6.8 percent among overweight adolescents and 28.7 percent among obese adolescents.¹⁰ However, these rates may underestimate the current extent of the problem, because both the magnitude and the prevalence of childhood obesity have increased in the past decade.

Epidemiologic data show that 4 percent of all adolescents and 30 percent of overweight adolescents in the United States have the metabolic syndrome.⁹ Prevalence among 12 to 19 year olds in the United States is about 4.2 percent.¹⁰ The risk of the metabolic syndrome is nearly 50 percent in severely obese (BMI >40.6 kg/m²) adolescents.³⁰

The prevalence of the metabolic syndrome also increased significantly with increasing insulin resistance.

The Medline and Embase databases were searched for articles published between August 2007 and January 2009, in which the prevalence of the metabolic syndrome was analyzed in populations aged between 2 and 19 years, using several recognized definitions. Diagnostic criteria were extracted for the Met S and prevalence rates by sex, age group, body mass index status and ethnicity. A total of 36 studies were included. The prevalence estimates from general population and community-based sampling ranged from 1.2 to 22.6 percent with rates of up to 60 percent observed in the overweight and obese.³⁰

Singh et al screened 1083 adolescents between 12 to 17 years of age in Chandigarh, India. The overall prevalence of MS in adolescents was 4.2 percent. However, the prevalence rose to 5.8 percent when the fasting plasma glucose cut-off was lowered to 5.5 mmol/L. There was no gender difference in the distribution of MS. When stratified by body mass index (BMI), 5.5 percent adolescents had a BMI >95th percentile, while 4 percent had a BMI between 85th and 95th percentile. Of the adolescents with BMI >95th percentile, 36.6 percent met the criteria for MS, while 11.5 percent met the criteria in those with a BMI between 85th to 95th percentile. Only 1.9 percent of the normal population had MS (P <0.0001).

Low high-density lipoprotein was the most common and abdominal obesity the least common constituent of MS.³¹

COMPONENTS OF METABOLIC SYNDROME IN CHILDREN

Obesity

Etiological Role of Weight Gain and Obesity in Metabolic Syndrome

For most patients, the root causes of the metabolic syndrome are improper nutrition, inadequate physical activity, and subsequent increases in body weight.

As the degree of obesity increases, the prevalence of Met S increases, with obesity occurring in 38.7 percent of moderately obese (mean body mass index [BMI] 33.4 kg/m²) and 49.7 percent of severely obese (mean BMI 40.6 kg/m²) children and adolescents.

Among obese children, the prevalence of the metabolic syndrome is high and increases with worsening obesity.^{10,20} This was illustrated in a study of 439 obese, 31 overweight, and 20 normal-weight children and adolescents who underwent a comprehensive metabolic assessment.²⁰ The metabolic syndrome was present in 39 and 50 percent of the moderately and severely obese subjects, respectively. In contrast, no overweight or normal-weight children met the criteria for the metabolic syndrome.

Morrison et al³² carried out a prospective assessment of 814 children and adolescents as part of a 25 to 30 year follow-up. Metabolic syndrome in adulthood was strongly associated with presence of metabolic syndrome and with body mass index (BMI) in childhood, with each increase in BMI percentile of the order of 10 points being linked to a 25 percent increase in the risk of metabolic syndrome in adulthood. Another important finding from this study was that metabolic syndrome in childhood was an independent predictor of DM2 in adulthood.³²

DYSLIPIDEMIA

The lipid profile associated with the metabolic syndrome puts individuals at increased risk for cardiovascular disease. Several deleterious changes in lipid metabolism are often seen in obese individuals. These changes are more closely correlated with the amount of visceral fat than total body fat. In general, obesity tends to elevate fasting plasma total cholesterol and TGs, and reduce plasma HDL-cholesterol levels. Though plasma LDL-cholesterol levels remain slightly elevated or normal, small, dense atherogenic LDL particles tend to increase, particularly in patients with insulin resistance associated with visceral adiposity. The low HDL-C levels, high LDL-C to HDL-C ratio, and high proportion of small, dense LDL particles increase risk for atherosclerosis.

The Bogalusa Heart Study, a community-based study of risk factors for cardiovascular disease, pooled data from 9167 subjects aged 5 to 17 year. These investigators found that children with a BMI above the 85th percentile for age and gender were more likely to have adverse levels of cholesterol, LDL-cholesterol, HDL-cholesterol, TG, and blood pressure, respectively, than normal weight subjects.³³

Insulin Resistance

Hyperinsulinism and insulin resistance are characteristic features of obesity.³⁴ It has been demonstrated that insulin secretion increases as the severity of obesity increases and this increase in insulin secretion is accompanied by varying degrees of resistance to insulin mediated glucose uptake, resulting in abnormalities in glucose tolerance in some obese adolescents.³⁵ Insulin resistance results in the development of acanthosis nigricans, a raised hyperpigmentation of the skin often present at the back of the neck, axillae and other flexural areas. Girls with hyperinsulinism may develop hyperandrogenism and hirsutism. Occasionally, some adolescents with a familial predisposition to type 2 diabetes develop the disease.

About 25 percent of children or adolescents with obesity have insulin resistance, and 4 percent have silent type 2 diabetes.³⁶ As in adults, insulin resistance and diabetes are associated with other elements of the metabolic syndrome, including hypertension and abdominal fat distribution. Studies in children have shown a relationship among fasting insulin and lipids³⁷ blood pressure³⁸⁻⁴⁰ and BMI.^{41,42} Furthermore, high insulin levels have been shown to precede the development of the atherogenic profile characterized by low HDL-cholesterol, high triglycerides, and high systolic blood pressure. Hyperinsulinemia, through stimulation of arterial smooth muscle proliferation, has been implicated in the development of atherosclerotic plaque and degree of insulin resistance is significantly correlated with coronary artery disease.

The mechanism through which insulin resistance and the accompanying hyperinsulinemia may alter blood pressure is less clear but may relate to direct effects on the sympathetic nervous system and renal sodium reabsorption. High blood pressure may develop due to the lack of resistance to these secondary effects of insulin or alternatively, insulin resistance may lead to endothelial dysfunction through the nitric oxide pathway.

Systemic Arterial Hypertension

The association between arterial hypertension and obesity is valid for all age groups. In the pediatric population, obesity is the primary cause of hypertension. Systolic hypertension is positively correlated with BMI and the waist- to-hip ratio in both children and adolescents.^{43,44}

Arterial hypertension in children is defined statistically on the basis of a distribution curve from healthy

children. Body composition is the greatest determinant of arterial blood pressure in children and adolescents. For this reason, arterial blood pressure measurements must be adjusted for height, age and sex. ([http://www.nhlbi.nih.gov/guide lines/hypertension/child_tbl.htm](http://www.nhlbi.nih.gov/guide%20lines/hypertension/child_tbl.htm)).

Endothelial Dysfunction

Endothelial dysfunction is one of the earliest signs of increased risk for cardiovascular disease and has been shown to be predictive of cardiovascular events. Endothelial dysfunction develops in the milieu of cardiovascular risk factors such as obesity, hypertension, dyslipidemia, insulin resistance, and type 2 diabetes. Moreover, obese children have increased levels of hemostatic and inflammatory factors, including fibrinogen, plasminogen activator inhibitor 1, and C-reactive protein.^{43,45,46} These factors may contribute to endothelial dysfunction and early atherogenesis in obese youth. In obese children, endothelial dysfunction is related to the severity of obesity, as well as to the degree of insulin resistance.

ASSOCIATIONS AND FUTURE OUTCOMES OF METABOLIC SYNDROME

Hepatic Manifestations

Recent studies have revealed the hepatic manifestations of the metabolic syndrome, which include nonalcoholic fatty liver disease (NAFLD) and nonalcoholic steatohepatitis (NASH).^{47,48}

A valuable biomarker for both of these disorders is an elevated alanine aminotransferase (ALT) level.⁴⁹

Between 10 and 25 percent of obese children have elevated transaminases, primarily ALT; the degree of obesity is related to the prevalence of elevated ALT levels; studies have shown that 11 percent of the moderately obese subjects and 21 percent of the severely obese subjects have elevated ALT levels.

Abdominal sonography can detect a fatty liver, which is also associated with a greater BMI, in 52 percent of obese children. In an autopsy study, the incidence of fatty liver was 38 percent in obese children 2 to 19 years of age. Morbidly obese children are particularly prone to fatty liver. Weight reduction is an effective treatment for NAFLD. Although a benign clinical course is typical of NAFLD, it may be associated with increasing fibrosis and, rarely, progression to cirrhosis.

Cardiovascular Consequences of Obesity (Relationship between Components of MS and Future CV Outcomes)

A recent study prospectively analyzed a cohort of 276,835 children for coronary disease. The risk of a coronary event in adulthood had a positive correlation with BMI between

7 and 13 years of age for boys and between 10 and 13 years of age for girls, with a linear relationship between BMI and the rate of cardiac events.⁵⁰

Another interesting study estimated the prevalence of obesity among 35-year-old in the United States in 2020 (projected from current data and secular trends) and the future incidence of coronary events between 2020 and 2035 (using a computerized statistical simulation program). The study concluded that in 2035 the prevalence of coronary disease would have risen by 5 to 16 percent, with an excess of 100,000 cases being attributable to the increase in obesity.⁵¹

The greatest concern aroused by childhood obesity is probably cardiovascular diseases. The Bogalusa Heart Study⁵² analyzed data from autopsies of people who died aged from 3 to 31 and who had previously been assessed for risk factors (lipid profile, arterial blood pressure, anthropometric data). The study results showed that the presence of fatty streaks (one of the earliest stages of atheromatous plaques) in the aorta was strongly related to total cholesterol and LDL-cholesterol levels and correlated inversely with HDL-cholesterol. Fibrous plaques were observed in the coronary arteries of people who had high LDL-cholesterol, triglycerides and arterial blood pressure and low HDL. Microscopic histological analysis of the aortic and coronary intima confirmed these findings.

The Muscatine Study demonstrated that cardiovascular risk in adults is related to childhood LDL-cholesterol levels and childhood BMI in females.⁵³

The Cardiovascular Risk in Young Finns Study also showed that childhood LDL-cholesterol and BMI correlated with adult cardiovascular disease. The increased cardiovascular risk in adulthood was irrespective of adult risk factor status, indicating that permanent damage to the arterial wall may occur during childhood.

Postmortem studies in children showed that 50 percent of children age 2 to 15 year had fatty streaks in their coronary arteries, and 8 percent of these children had raised fibrous plaques in their coronary arteries. The Pathobiological Determinants of Atherosclerosis in Youth study found that 12 percent of adolescents age 15 to 19 year had raised lesions or advanced lesions of atherosclerosis in their right coronary arteries.⁵⁴ In both of these postmortem studies, the extent and severity of lesions correlated with BMI and lipoprotein levels.

Evaluation of the Obese Child for Metabolic Syndrome

A comprehensive medical evaluation must be done in all obese children and adolescents to screen for metabolic syndrome and other associated complications.

Approach to evaluation of an obese child, screening for complications that comprise the metabolic syndrome

and management and prevention of obesity have been discussed in the chapter on "obesity".

Management of Metabolic Syndrome

The main goal of therapy should be to achieve the objective of lifelong weight control.

The combination of dietary and physical activity interventions appears to provide the most beneficial improvements in components of the Met S. Comprehensive behavioral modification in overweight children reduces body weight, improves body composition, and positively modifies many of the components of the Met S within 3 months, and these effects are maintained at 1 year.⁵⁵ Similar effects have been observed for endothelial dysfunction, with the greatest improvements occurring when combined dietary and exercise interventions are used in overweight children.⁵⁶

Therefore, it is reasonable to suggest that early intervention aimed at managing obesity could reduce the risk of developing the MS. It is conceivable that even in the absence of weight loss, overweight and obese children may improve their cardiovascular risk profile by lifestyle changes and therapies targeted toward individual components of the syndrome.

At the present time, there is no specific treatment for this clustering of risk factors in children, other than reducing obesity, increasing physical activity, and treating the various components of the Met S such as hypertension or hyperlipidemia. Weight control improves glucose tolerance, with a recommended weight loss in adults of 10 percent to 15 percent. Exercise training improves insulin sensitivity and endothelial vascular function beyond the benefits of glycemic control and blood pressure reduction in adults and children.^{57,58} In small studies, metformin has been used effectively in adolescents with T2DM to decrease BMI and improve glucose tolerance.^{59,60}

Disorders of Sexual Differentiation

Anurag Bajpai

INTRODUCTION

Disorders of sexual differentiation (DSD) are one of the most challenging conditions encountered by the pediatrician. The condition is relatively common with a prevalence of 1 in 300 to 5000 live births depending upon the criteria used. Genital ambiguity is not only a medical but also a social emergency. The first question that comes to the mind after the birth of the child invariably pertains to the gender of the newborn child. Inappropriate counseling in the immediate postnatal period therefore, leaves permanent scars in the minds of the parents. The management of an infant with DSD is thus as much an art as science. An understanding of physiology of sexual differentiation is mandatory for comprehensive management of the condition.

SEXUAL DIFFERENTIATION

The major steps in sexual differentiation include determination of genetic sex, development of gonads in accordance to genetic signals and subsequent differentiation of sexual characteristics. Deviation at any of these levels results in discordance of genetic, gonadal and phenotypic sex culminating in DSD.

Gonadal Development

The process of sexual differentiation begins with the development of bipotential gonad. Germ cells arise from the celomic epithelium of allantois, a part of hind gut and migrate to the urogenital ridge at four to six weeks of gestation. There they combine with somatic cells to give rise to the bi-potential gonad. Sex determining region of Y chromosome (SRY), a transcription factor in the short arm of Y chromosome is the chief regulator of sex determination. In boys, SRY gene induces testis determining genes like SOX9 while inhibiting anti testis gene DAX1 resulting in the development of gonad into testis. In the absence of

SRY, the gonads develop into ovaries under the influence of *DAX1* genes. The somatic cells give rise to Sertoli and Leydig cells in males in the presence of SRY gene and into granulosa and theca cells in females in its absence.

Development of Internal Genitalia

Sertoli cells secrete anti-mullerian hormone (AMH), which is responsible for the regression of mullerian duct in males. Testosterone secreted by Leydig cells stabilizes wolffian structures and induces their differentiation into epididymis, vas deferens, ejaculatory ducts, and the seminal vesicles. In the absence of AMH and testosterone mullerian ducts differentiate into fallopian tubes, uterus and the upper third of the vagina along with regression of the wolffian ducts.

Development of External Genitalia

Dihydrotestosterone (DHT), potent androgen produced by the action of enzyme 5 α reductase on testosterone, is the chief regulator of external genitalia development in males. DHT induces the development of corpus spongiosum, penile corpus cavernosa and scrotum. In girls, the labioscrotal swellings and urethral folds do not fuse in the absence of androgens and give rise to labia majora and minora, respectively. The genital tubercles form the clitoris while canalization of the vaginal plate creates the lower portion of the vagina.

CLASSIFICATION

DSD can result from disorders of gonadal development, gonadal function or hormone action. Traditionally a morphology based classification of DSD has been employed that divided these patients into virilization disorders, feminization disorders and true hermaphroditism. Besides being ambiguous, these terms have the disadvantage of negative connotations. There was thus a move towards

developing culturally acceptable classification of these disorders. This culminated in the consensus statement on disorders of sexual development with etiopathological classification of DSD (Table 1, Flow chart 1).

46 XX DISORDERS OF SEXUAL DIFFERENTIATION

These disorders are most commonly caused by fetal or maternal androgen excess; SRY insertion and 46 XX gonadal dysgenesis are rare cause of 46 XX DSD.

Androgen Excess

Intrauterine androgen excess could due to increased fetal androgen production or transplacental passage of androgens. *Congenital adrenal hyperplasia* is the most common

cause of DSD (Table 2). 21-hydroxylase deficiency, accounting for 95 percent of children with CAH, is characterized by glucocorticoid and mineralocorticoid deficiency on one hand and androgen excess on the other. Patients with the most severe form present in the neonatal period with life-threatening salt wasting. 11-hydroxylase deficiency, 3 β -hydroxysteroid dehydrogenase deficiency and *P450 oxidoreductase deficiency* are other forms of CAH presenting with 46 XX DSD. These disorders are diagnosed by the estimation of basal and ACTH stimulated 17OHP levels (21-hydroxylase deficiency) or 11 hydroxy DOC (11 hydroxylase deficiency). Mullerian structures are normally developed providing an opportunity for fertility. *Aromatase deficiency*, deficiency of enzyme converting testosterone to estrogen, results in androgen excess and maternal and fetal

Table 1: Classification of DSD ESPE-LWPES consensus statement 2005

Category	Previous names	Disorders
Sex chromosome DSD		45 XO Turner syndrome 46 XX/XY gonadal dysgenesis
Ovotesticular DSD 46 XY DSD	True hermaphroditism Male pseudohermaphroditism Feminization Undervaluation	Gonadal dysgenesis Steroidogenic defects AIS, 5 AR II deficiency
46 XX DSD	Female pseudohermaphroditism Variation	Androgen excess Aromatase deficiency SRY insertion

AIS- Androgen insensitivity syndrome, CAH- Congenital adrenal hyperplasia

Flow chart 1: Etiology based classification of DSD

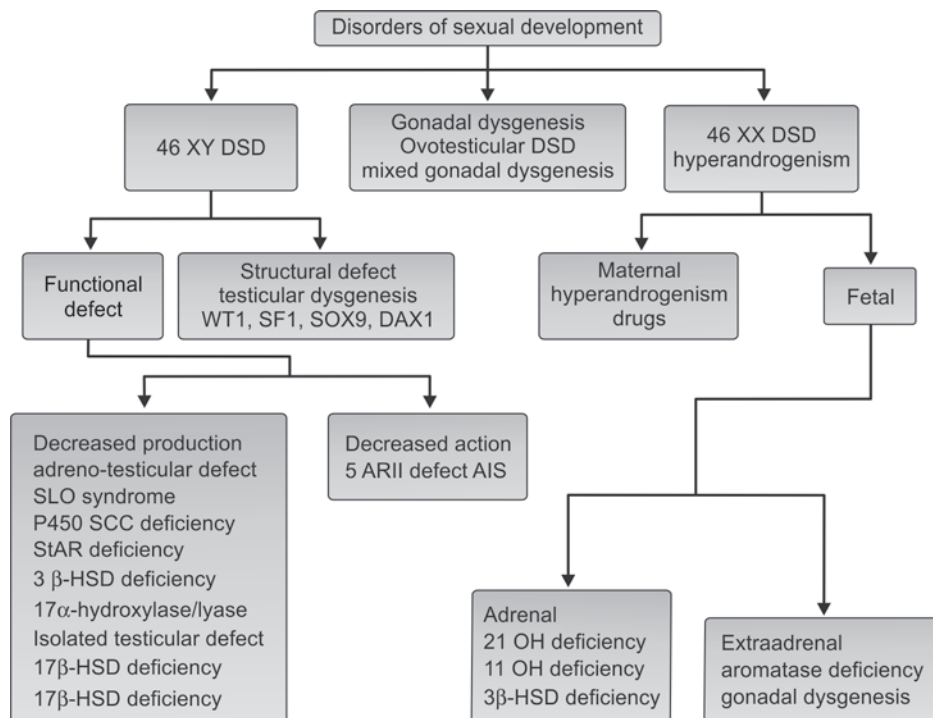

Table 2: Steroidogenic defects associated with DSD

Enzyme	Features	Diagnostic test
Associated with under civilization		
7 DHC dehydrogenate SLO syndrome	Polydactyly, microcephaly Sex reversal	High 7 dehydrocholesterol
P450 SCC deficiency	Adrenal insufficiency Complete sex reversal	Low DHEA, pregnenolone, 17OHP
StAR	Adrenal insufficiency Complete sex reversal	Low DHEA, pregnenolone, 17OHP
17 hydroxylase	Hypertension	Low 17OHP, high deoxycorticosterone
17β-HSD III	Complete sex reversal	Low testosterone, high androstenedione
5 α reductase	Virilization at puberty	High testosterone to DHT ratio
Associated with virilization		
21 hydroxylase	Adrenal insufficiency	High 17OHP
11β-hydroxylase	Hypertension	High deoxycortisol
Associated with both virilization and under virilization		
3β-HSD	Adrenal insufficiency	High 17 OH pregnenolone, DHEA
P450 Oxidoreductase deficiency	Adrenal insufficiency	High 17OHP and low androstenedione
SLO- Smith-Lemeli-Optiz syndrome, 17OHP-17-hydroxyprogesterone, DHEA- Dehydroepiandrosterone, DHT- Dihydrotestosterone		

virilization. *Transplacental* exposure to androgens is most commonly associated maternal medications or hyperandrogenism in mother due to luteoma of pregnancy or androgen producing tumor.

Gonadal Dysgenesis

46 XX males have a prevalence of 1 in 25000 males and usually present with infertility. The condition is most commonly associated with SRY insertion.

46 XY DISORDERS OF SEXUAL DIFFERENTIATION

These disorders are caused by abnormalities in testicular development, androgen production and androgen action. Unfortunately, the diagnosis of a substantial number of these individuals can not be identified despite extensive evaluation.

Gonadal Dysgenesis

Gonadal dysgenesis is the most common cause of 46 XY DSD. SRY deletion is however identified in only 15 to 20 percent of 46 XY females. Multisystem involvement is observed in gene defects affecting the WT1 (glomerulopathy and hemihypertrophy), SF1 (adrenal insufficiency) and SOX9 genes (skeletal dysplasia). There is a high risk of development of gonadoblastoma in 46 XY DSD mandating the need for gonadectomy. *Vanishing testis syndrome* is characterized by destruction of testis during an embryonic period. Genital ambiguity may occur if testes are destroyed between 8 to 14 weeks of gestation. These patients may be differentiated from those with cryptorchidism based on undetectable AMH levels.

Defective Androgen Synthesis

Fetal androgen deficiency could be related to LHCG receptor mutation, defective adrenal and testicular steroidogenesis (P450 side chain cleavage enzyme, StAR, P450 SCC, 17-hydroxylase/lyase and 3 β -hydroxysteroid dehydrogenase deficiency) or isolated testicular steroidogenic defect (17 β -hydroxysteroid dehydrogenase deficiency). Adrenal steroidogenic defects presents with salt wasting mandating early identification of the condition. 17 β -hydroxysteroid dehydrogenase deficiency is characterized by virilization during puberty due to extra gonadal conversion of androstenedione to testosterone.

Inefficient Androgen Action

Inefficient androgen action may be due to androgen resistance (androgen insensitivity syndrome) or impaired conversion of testosterone to dihydrotestosterone (5 alpha reductase deficiency) *Androgen insensitivity syndrome (AIS)* is an X-linked disorder characterized by resistance to androgen action. The disease forms a spectrum ranging from apparently normal phenotypic female (complete AIS) to genital ambiguity to a male with hypospadias (partial AIS). Complete AIS may present with inguinal hernia in young girls or primary amenorrhea in older girls. Absent or sparse pubic and axillary hairs are characteristic of the condition due to the pivotal role of androgens in their development. Genital ambiguity or infertility in maternal relatives may be present suggesting X-linked inheritance. Mullerian structures are absent as AMH action is normal. High testosterone and DHT levels are suggestive; the diagnosis is established by demonstration of decreased

enzyme activity on skin fibroblast. 5 Alpha reductase deficiency presents as a spectrum of disease ranging from a male with penoscrotal hypospadias to an under feminized female. Increased testosterone during puberty acts on the androgen receptor leading to virilization. Elevated testosterone in the setting of low DHT is diagnostic (Table 2).

Ovotesticular Disorders of Sexual Differentiation

The condition is characterized by the presence of both testicular and ovarian tissue in the same individual. The most common karyotype is 46 XX. Other combinations include 46 XX/XY, 46 XYY and others. The presentation is usually with genital ambiguity. Genital asymmetry is characteristic. Thus, mullerian structures may be present on the side of ovary while wolffian structures may develop along side the testis.

EVALUATION

Evaluation of a child with DSD begins from the labor room. Compassionate and patient counseling is mandatory to achieve parental confidence. 21-hydroxylase deficiency should be excluded to prevent life threatening consequences.

When to suspect?

Most children with DSD have obvious genital ambiguity. DSD should however also be considered in girls with clitoromegaly and posterior labioscrotal fusion, boys with penoscrotal hypospadias (suspected 46 XY DSD) and cryptorchidism (46 XX DSD with hyperandrogenism) and girls with bilateral inguinal masses or primary amenorrhea with normal pubertal development (complete AIS). Discordance between karyotype and phenotypic sex should prompt evaluation for DSD even if genital appearance is normal. It is also important to identify normal variants like prominent but not enlarged clitoris (Fig. 1), apparent small penis embedded in suprapubic fat, appearance of clitoromegaly in preterm girls and labial adhesion without clitoromegaly to avoid unnecessary work-up.

Clinical Evaluation

Family history of consanguinity and genital ambiguity should be recorded. Congenital adrenal hyperplasia is likely if there is a family history of sibling deaths and consanguinity. Exaggerated pubertal gynecomastia and DSD in maternal relatives (brothers and maternal uncle) is suggestive of androgen insensitivity syndrome. Gonads in patients with complete androgen insensitivity are often mistaken for inguinal hernia and operated upon. Intake of progestational drugs during first trimester and features of virilization in mother should be enquired. Failure to thrive, polyuria and lethargy suggest the possibility of 21-hydroxylase deficiency (Fig. 2).

Fig. 1: This two-week-old girl was referred for evaluation of clitoromegaly. She was diagnosed as prominent clitoris. On follow-up at the age of six months, the girl had normal genital appearance (For color version see plate 13)

Fig. 2: This three-week-old neonate presented with genital ambiguity. Examination revealed Prader stage IV genitalia, single urogenital opening, no palpable gonads and generalized hyperpigmentation. Investigations showed hyponatremia (sodium 112 mmol/L), hyperkalemia (potassium 6 mmol/L) and elevated 17OHP levels (200 nmol/L, 6000 ng/dl) confirming the diagnosis of salt wasting 21-hydroxylase deficiency (For color version see plate 13)

Virilization during puberty is suggestive of 5 α reductase and 17 β -hydroxysteroid dehydrogenase deficiency, while feminization during this period points to androgen insensitivity syndrome.

General Examination

General examination should be guided towards identification of pointers to disease (hyperpigmentation in steroidogenic defects, hemihypertrophy in WT1 defect, skeletal dysplasia in SOX 9 defect, polysyndactyly and mid facial narrowing in Smith-Lemeli-Optiz syndrome, Table 3). Pubic and axillary hairs are sparse in complete AIS while other secondary sexual characters are well developed.

Table 3: Pointers to diagnosis in DSD

<i>Pointer</i>	<i>Likely diagnosis</i>
Pigmentation	Congenital adrenal hyperplasia, SF1 defect
Genital asymmetry	Mixed gonadal dysgenesis, ovo testicular DSD
Skeletal dysplasia	SOX 9 defect
Polydactyly, microcephaly	Smith-Lemeli-Optiz syndrome
Hypertension	11 or 17 hydroxylase defect
Hemihypertrophy	WT1 mutation
Renal failure	Denys-Drash syndrome

This helps in differentiating this disorder from primary mullerian agenesis as a cause of primary amenorrhea in the presence of normal breast development. Examination of a neonate with genital ambiguity is incomplete without the examination of mother for features of hyperandrogenism in the form of hirsutism, acne and change in voice.

Genital Examination

Initial step in genital evaluation is directed towards identification of gonads. Bilaterally rounded structures below the inguinal canal are most commonly testis but may rarely be streak gonads or ovotestis. Unilateral gonads and genital asymmetry is suggestive of ovotesticular DSD. The labioscrotal region should be evaluated for the extent of fusion using the anogenital ratio (ratio of distance of anus from the posterior forchette to that anus to the base of phallus). Values above 0.5 are suggestive of virilization. The presence of mullerian structures can be confirmed by per rectal examination. The length and breadth of phallus should be measured. The number of openings in the urogenital region is helpful in deciding the presence of urogenital sinus. Asymmetrical labioscrotal region is suggestive of ovotesticular DSD (Fig. 3). The genitalia should be staged according to the classification proposed by Prader et al which divides these patients from grades I to V with grade I representing female with clitoromegaly and V male with cryptorchidism.

INVESTIGATIONS

Step-wise evaluation is required to establish the cause of DSD. Karyotype is the cornerstone of diagnosis of DSD but the results are usually available only after three to four weeks. Identification of Y and X material using FISH is helpful in rapid assessment. Ultrasound for mullerian structures and electrolytes should be done. Further evaluation is guided by the karyotype and presence/absence of palpable gonads and mullerian structures (Flow chart 2).

46 XX DSD with mullerian structures and no palpable gonad: The most important investigation is 17OHP with levels above 100 nmol/L (3000 ng/dl) suggesting the diagnosis of 21OHD while those between 20 to 100 nmol/L being

Fig. 3: This three-month-old boy presented with small phallic size (stretched penile length 1.5 cm), penoscrotal hypospadias and asymmetric genital appearance. Investigations were suggestive of gonadal dysgenesis (karyotype 46 XY/XO) (For color version see plate 13)

indicative of 11 β OHD. Urinary steroid profile is diagnostic in individuals with borderline 17OHP levels. Gonadal biopsy is indicated if 17OHP levels are normal to exclude gonadal dysgenesis.

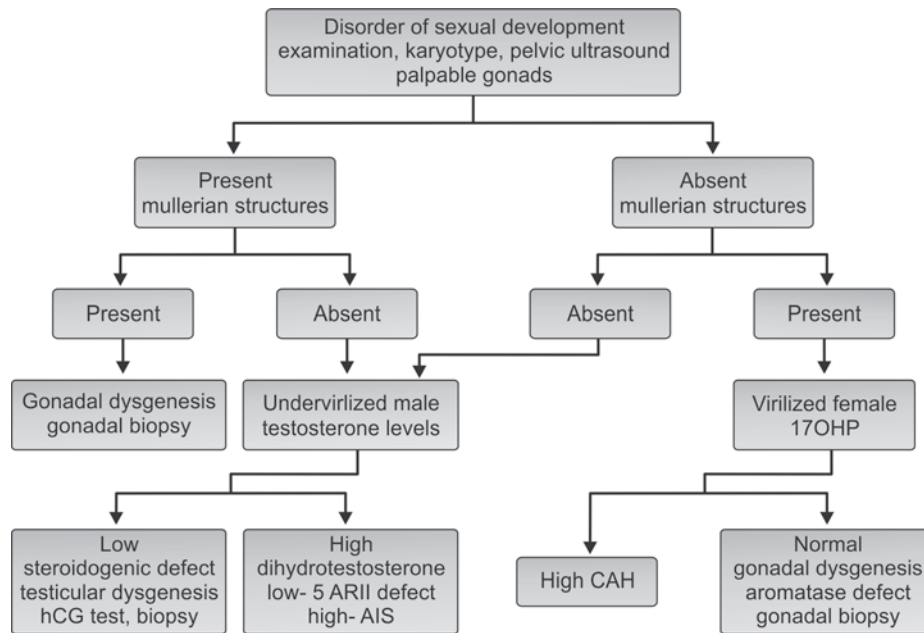

46 XY DSD with no mullerian structures with/without palpable gonads: Work-up is guided by serum testosterone levels. Low testosterone indicates gonadal dysgenesis or steroidogenic defects while high levels are suggestive of inefficient testosterone action. Antimullerian hormone should be done in children with low testosterone to detect sertoli cell functions. Abdominal ultrasound and urine protein should be measured to assess association with Denys Drash syndrome and WT1 gene defect. HCG stimulated testosterone to DHT ratio are indicated in individuals with elevated testosterone levels with elevated ratio suggesting 5 alpha reductase deficiency.

46 XX/XY karyotype with mullerian structures and palpable gonads: This constellation of findings indicates the diagnosis of ovotesticular DSD and mandates gonadal biopsy.

MANAGEMENT

Components of management include management of life-threatening conditions, initiation of specific treatment, parental education and decision about gender of rearing. The managing team should include pediatric endocrinologist, pediatric surgeon with expertise in DSD, social worker and geneticist. Salt wasting CAH should be identified and treated. Premature gender assignment and mention of gender specific words should be avoided. Parents should be reassured that the child should be able to achieve normal outcome. Parental education should include physiology of sexual development, disorders of

Flow chart 2: Approach to a child with DSD

sexual differentiation, presumptive diagnosis, and potentials for sexual function and fertility.

Decision Regarding Gender of Rearing

The considerations include ability to perform sexually, fertility prospects, feasibility of genital reconstruction and social considerations (Table 4). Fertility prospects are limited to individuals with 46 XX DSD who should be reared as females. Rarely male gender of rearing may be considered in extremely virilized 46 XX DSD individuals (Prader IV and V) with delayed diagnosis. 46 XY individuals with complete AIS should be reared as females. In all other 46 XY individuals with DSD male sex of rearing is preferred given the programming effects of intrauterine androgen exposure. A trial of androgens could be given in individuals with very small penile size with increase in size indicating male sex of rearing.

Medical Management

Steroid replacement should be done in children with congenital adrenal hyperplasia. Trial of testosterone should be given in patients with 46 XY DSD. Age and gender appropriate pubertal induction and hormone replacement therapy is required to achieve normal long-term outcome.

Table 4: Guidelines for gender of rearing for DSD

Disorder	Considerations	Gender of rearing
CAH with virilization	Fertility as female Usually gender appropriate	Female
Undervirilized male	Usually infertile Variable gender preference	Testosterone response Present—as male Absent—as female
Complete AIS	No prospect of fertility Risk of gonadoblastoma	Female Gonadectomy
Partial AIS	No fertility prospect May respond to androgens	Male
5 α Reductase defect	Virilization during puberty	Male

Surgical Procedures

Surgical reconstruction should be considered only when necessary. Mild clitoromegaly does not require surgery. Clitoroplasty should be done as soon as feasible. Vaginal size should be assessed during puberty to decide about

the need for vaginoplasty. Undervirilized boys should be taken up for hypospadias and cordee correction after a course of testosterone (25 mg intramuscularly monthly for three doses). Gonadectomy is indicated in individuals with Y line at risk for gonadoblastoma. Prophylactic gonadectomy should be performed at an early age in 46 XY gonadal dysgenesis. The risk of gonadoblastoma is low in complete AIS and the procedure may be deferred till puberty to allow for estrogenization.

There has been a tremendous increase in the understanding of the process of sexual differentiation. This has resulted in identification of specific etiology in a large number of cases. Careful clinical assessment and patient counseling however remains cornerstone to successful management of a child with DSD.

Newborn Screening for Endocrinopathies

Sudha Rao Chandrashekhar

INTRODUCTION

Newborn screening (NBS) is a race against time. It is a diversified and ever expanding aspect of child health care. Screening for treatable congenital endocrinopathies is an important preventive health measure which not only prevents mortality and improves quality of life of the affected individual but also the social health. Effective newborn screening requires an adequate public health infrastructure integrated with the health care delivery system. In India, we still do not have a health mandate for universal newborn screening.

The universal screening of all newborns dates back to the history of phenylketonuria (PKU) a metabolic error with devastating effects. Horst Bicket in 1953, first described an effective dietetic therapy for PKU. It was soon realized that treatment prior to the onset of symptoms helped long-term outcome. In early 1960s Robert Guthrie and Ada Susi developed a biological test for phenylalanine and the now famous Guthrie card, and thus began the concept of universal newborn screening.¹ A major breakthrough occurred in the early 1970s when Dussault et al added a radioimmunoassay for thyroxine (T_4) and later thyrotropin (TSH) and screening for congenital hypothyroidism (CH) was added.² In 1977, serum 17 hydroxy progesterone (S-17OHP) was added to screen for congenital adrenal hyperplasia (CAH).² As more and more diseases were found to be treatable, if detected in presymptomatic stage, an ever expanding list of conditions were included which were diverse and rare. Introduction of tandem mass spectrometry (TMS), in 1980s, made it possible to test for a large number of metabolic disorders. Presently more than 30 diverse disorders can be screened in the various 206 NBS programs worldwide.

NEWBORN SCREENING GUIDELINES

Screening of newborns is not only about the test but also follow up, treatment and evaluation. There have been many guidelines issued regarding the same.^{3,4}

The principles of population-wide screening for disease formulated by Wilson and Jungner in 1968 (WHO guidelines) remain valid today. Any disease for which screening is performed must be a serious condition whose etiology and pathogenesis are understood, which becomes clinically manifest only after a latent or early symptomatic stage, which can be treated successfully with the available medical and organizational resources, and for which suitable testing methods exist.³

These fundamental pre-requisites are fulfilled by CH and CAH the two congenital endocrine disorders which are included in the NBS panel in many countries.

CONGENITAL HYPOTHYROIDISM

Congenital hypothyroidism (CH) is one of the most common preventable causes of mental retardation when treated early and adequately. The incidence of CH is one in 2,500 to 4,000 newborns in most populations, and is more common in India with an incidence of one in 1,100 to 1,200 newborns.⁵ CH can be transient or permanent. Permanent disorders are more common and are due either to structural defects like thyroid gland agenesis/dysgenesis or functional defect of thyroid hormonogenesis. Transient hypothyroidism is less common and occurs due to trans-placental transfer of maternal antibodies, drugs or states of iodine deficiency or excess. A small number of children have CH due to hypothalamo pituitary dysfunction.

Only 10 to 15 percent of hypothyroid neonates present with diagnostic clinical features and often the signs and symptoms are nonspecific.⁵ Many clinical scores have been developed to assist in diagnosis. The following clinical score used in the newborn period, is suggestive of hypothyroidism at a score of more than 5.

Studies have revealed that about 10 percent children are diagnosed clinically in the first month of life and 30 percent in the first 3 months. L-thyroxine replacement

Apgar score for hypothyroidism	Score
Open posterior fontanelle	1
Umbilical hernia	2
Typical edematous facies	2
Constipation	2
Female sex	1
Pallor, hypothermia	1

Hypotonia	1
Prolonged jaundice	1
Rough, dry skin	1
Postmaturity	1
Large baby (weight >3.5 kg)	1

therapy if started before 3 months of age, the mean intelligence quotient (IQ) is 89 and drops to 70 when treated between 3 to 6 months of age and is as low as 54 if initiated therapy after 6 months of postnatal life.⁶ Hence, there is a high-risk of delayed diagnosis and treatment based on clinical examination alone.

In addition to the profound clinical benefit, it has been estimated that the cost of NBS for CH is much lower than the cost of diagnosing CH at an older age thus, having the highest cost benefit ratio. In India, we still do not have a health mandate necessitating CH screening of every newborn by law. Hence newborn screening for CH is done differently at different centers across the country.

Screening two Strategies for Congenital Hypothyroidism

There are two primary approaches to neonatal screening for hypothyroidism:

- *Primary measurement of T_4* , followed by determination of TSH if the T_4 value is low. This approach is being used in North America for screening.
- *Primary measurement of TSH*, followed with T_4 measurement if TSH levels are high. This method is followed in most parts of Canada, Europe and Japan.

Both approaches have their advantages and disadvantages and may miss out on a small number of cases.

A Third Approach is to Use Both T_4 and TSH at the First Screen

It is important to note that positive predictive value (PPV) depends on the prevalence of CH regardless of the choice of the screening strategy used.

T_4 Screening

Advantages

- Detects secondary and tertiary hypothyroidism
- Detects TBG deficiency
- Detects hyperthyroxinemia.

Disadvantages

- Can miss compensated hypothyroidism
- Can miss late onset hypothyroidism as occurs in Down syndrome
- Recall rate is higher 0.3 percent.

TSH Screening

Newer generation of TSH assay techniques have improved the sensitivity with lower recall rates and very less false negative test results.

Advantages

- Can detect compensated hypothyroidism
- Recall rate is 0.05 percent.

Disadvantages

- Can miss secondary or tertiary hypothyroidism
- Can miss TBG deficiency
- Hypothyroxinemia
- Hyperthyroidism may be missed
- Miss delayed TSH rise as seen in LBW or VLBW babies.

Combined T_4 and TSH screening is ideal with can be undertaken in combined filter paper with multiplex bio-marker system. This method is more expensive.

AGE AT SCREENING

The preferred time for blood sampling is after 72 hours of life to decrease the number false positives which occurs due to physiological TSH surge.

In infants discharged from the nursery before 48 hours of age, blood should be obtained before discharge. In instances such as home births or in the case of a critically ill or preterm neonate, blood should be obtained by 7 days of age, recognizing that samples obtained after 4 days of age are late for screening of congenital adrenal hyperplasia or metabolic disease. Some centers in USA use two time periods, the second collection being done at 2 weeks of age. Infants with CH detected at the later screening time tend to be of LBW or VLBW, with mild or delayed TSH elevations.⁴

In most NBS, for CH the false positive to case ratio is 2 to 3:1.⁵ False negative results may be found if screening is done in very sick neonates or after having received blood transfusion.

Screening Sample

Either cord blood sample or heel prick sample on/after day 3 of life is collected on filter paper and checked for T_4 , TSH or both. If cord blood is collected it should be from the placental end. The filter paper designed for newborn screening bears printed circles. Capillary blood samples are placed in these circular areas to fill and saturate them. Spotting blood over a previous blood spot, or

double spotting, causes invalid results, and these blood spots should not be used.^{1,4}

Rescreening

As babies develop hypothyroidism despite a normal initial screen, many centers retest all the infants with normal thyroid screen at 4 to 6 weeks of age. Many affected infants are (1:30,000) detected by the second screening.

The American Academy of Pediatrics (2006)⁴ recommends that thyroid functions should be repeated during infancy, when there is a clinical suspicion of hypothyroidism

- History of thyroid disease during pregnancy
- Family history of thyroid dysmorphogenesis
- Infants with Down syndrome (high prevalence of late onset CH).

Interpretation of Results (Table 1)

Correct interpretation of the test results is very important and the pediatrician must be familiar with the normal changes occurring in the thyroid hormones soon after birth.

During the first hours after birth, there is an abrupt increase in pituitary TSH secretion, reaching levels of 60 to 80 mIU/ml within 30 minutes after delivery. This rise in TSH stimulates a 2 to 6 fold increase in secretion of T_4 and T_3 from the thyroid gland, by 24 hours of life. The T_4 levels are in the 15 to 19 $\mu\text{g/dl}$ range and T_3 levels in the 300 ng/dl range. TSH levels decline slowly over the next 72 to 96 hours, to <8 mIU/L by 5 to 7 days.

Babies with cord blood TSH of more than 35 mIU/ml or day 3 TSH of more than 20 mIU/ml should be retested for T_3 , T_4 and TSH.

Criteria for the Diagnosis of Congenital Hypothyroidism

Serum T_4 level <10 mcg/dl

Serum TSH >20 mIU/ml

Preterm babies have higher TSH with lower T_4 and T_3 values as compared to term babies due to immaturity of the hypothalamo-pituitary-thyroid (H-P-T) axis which occurs

in the second half of gestation and the feedback system which is complete only by second month of postnatal life.

Abnormal screening results may fall into the following categories:

- Low T_4 and increased TSH
- Low T_4 and normal TSH
- Normal T_4 and elevated TSH
- Low T_4 with delayed rise in TSH
- Transient TSH elevation.

LOW T_4 AND INCREASED TSH

Elevated TSH with low levels of T_4 and T_3 are suggestive of primary congenital hypothyroidism which may be permanent or transient.

Permanent primary CH (PPCH)

This is due to thyroid dysgenesis (80-90%) or dysmorphogenesis (10-20%).

Transient CH

In transient CH, T_4 levels are low and TSH is elevated, but they normalize spontaneously. These individuals are usually started on thyroxine replacement, only to be found to have normal thyroid functions later in life. This picture could be due to transplacental passage of thyroid antibodies, maternal iodine deficiency, excess exposure to iodine by the mother during pregnancy (iodine crosses the placenta and suppresses the fetal thyroid gland) or infant during the postnatal period, antithyroid drugs and dietary goitrogens.

LOW T_4 AND NORMAL TSH

Congenital TBG Deficiency

An X linked condition diagnosed by low TBG levels and normal free T_4 values. They are clinically euthyroid and do not need to be treated.

Transient Hypothyroxinemia of the Newborn

This is more common in low birth weight infants with or without prematurity, especially if they are sick, but may be present in a small number of normal newborns. This may not cause significant ill effects on the development of the newborn, hence routine supplementation may not be required, but they need to be followed up closely.

Central (Secondary-Tertiary or Hypopituitary Hypothalamic Hypothyroidism)

This results in deleterious effects on development if untreated. More often central hypothyroidism is associated with deficiency of other pituitary hormones. Patients with hypoglycemia, prolonged jaundice, micropenis, hypogonadism, diabetes insipidus, and other midline deformities must be worked up to rule out hypopituitarism.

Table 1: Interpretation of Results

T_4	Free T_4	TSH	Disorder
L	L	H	Primary hypothyroid
N	N	H	Transient/compensated hypothyroid
L	N	N	TBG low
L	L	N	Central hypothyroid; delayed TSH rise; transient hypothyroidism
H	H	N	Hyperthyroxinemia
H	H	H	T_4 resistance

Normal T_4 and Elevated TSH

Compensated hypothyroidism is the term used for patients with normal levels of T_4 and T_3 and elevated TSH. Such patients are clinically asymptomatic as long as their T_4 levels remain normal. TSH levels may remain elevated for a prolonged period of time or may normalize spontaneously later in life or may decompensate to develop full blown hypothyroidism. It is impossible to predict the course of these patients and they need to be evaluated thoroughly by an experienced pediatric endocrinologist to determine the need for treatment.

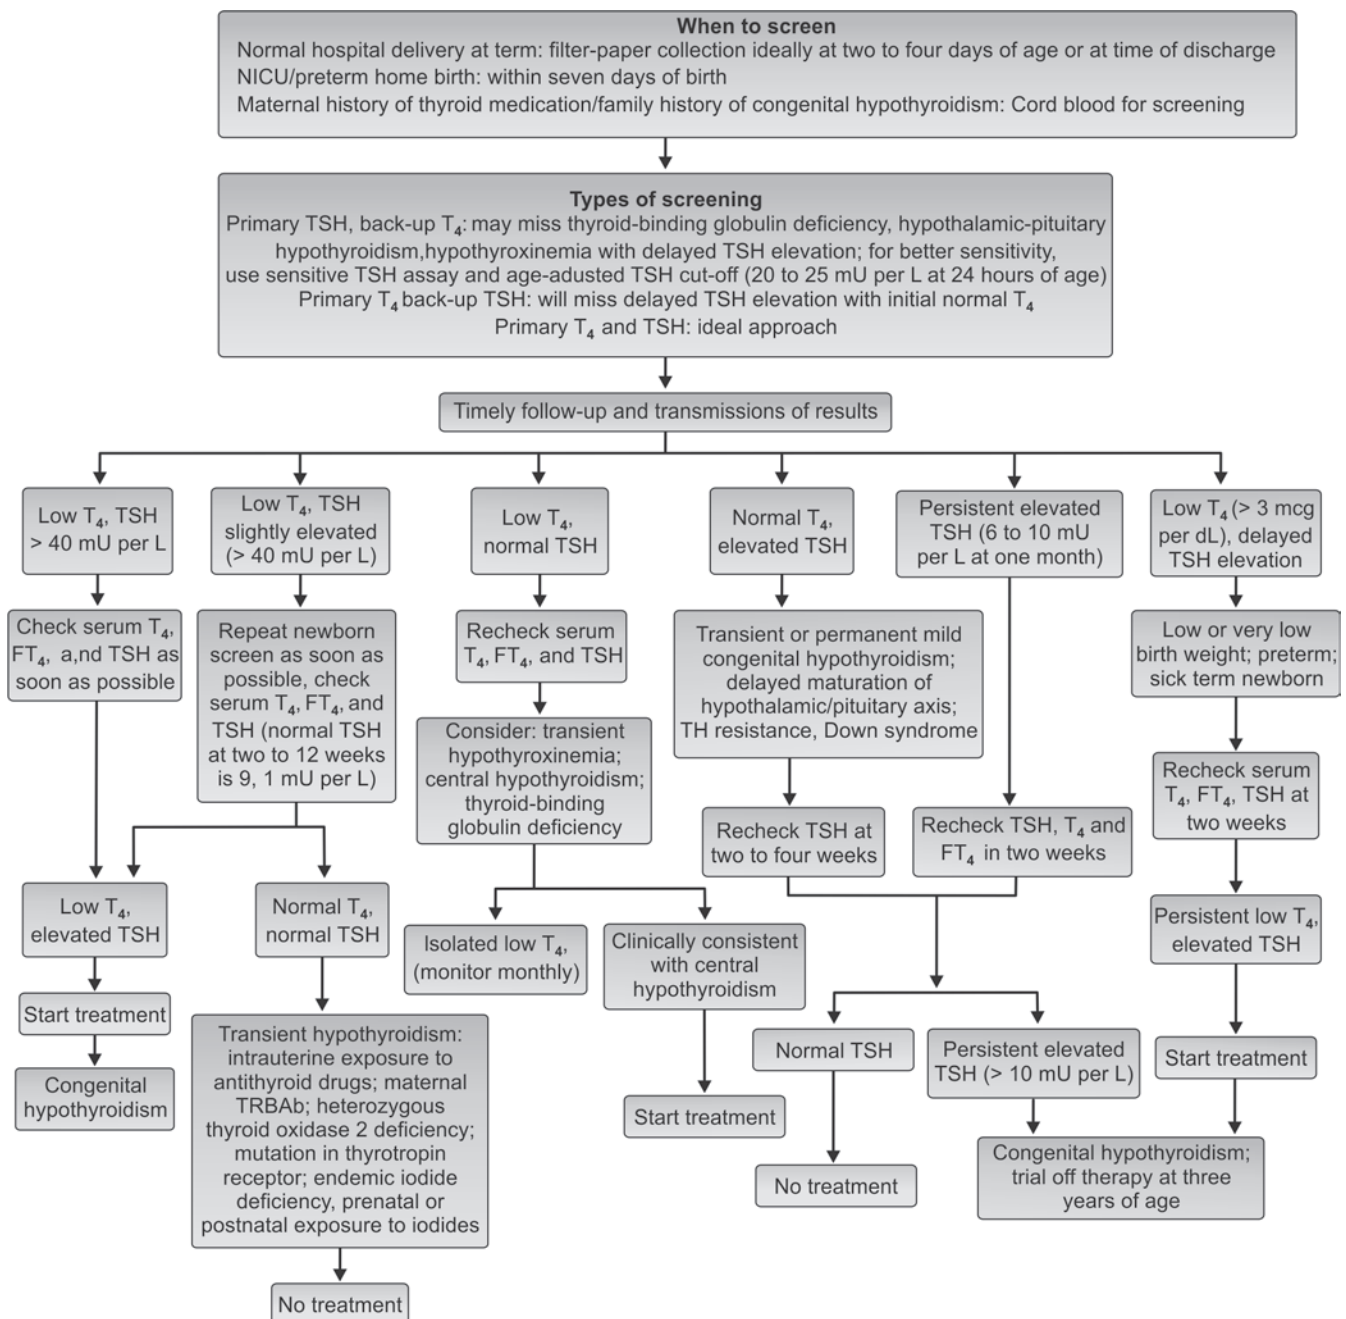

CLINICAL MANAGEMENT

As soon as the test results are available the infant must be seen by the pediatrician without delay. Pediatric endocrinologist referral is recommended (Flow chart 1).

Detailed history including prenatal thyroid status, maternal medications, maternal thyroid status and family history of thyroid disorders must be obtained. A thorough clinical examination must be done. Blood sample must be collected to recheck the thyroid status.

Thyroid ultrasonography, or iodine 123 (^{123}I) or sodium technetium 99m pertechnetate ($^{99\text{m}}\text{Tc}$) thyroid

Flow chart 1: Approach to newborn screening for congenital hypothyroidism

uptake scan may be undertaken to identify functional thyroid tissue.

Treatment need not be delayed to perform the scan. A thyroid scan can be performed within the first few days of treatment, because the elevated TSH found in patients with permanent CH rarely normalizes within this time period. A serum TSH measurement should be obtained at the time of the scan. If L-T4 therapy has caused the TSH concentration to be <30 mU/L, ultrasonography can still be performed. A scan can be performed after the child is 3 years of age, when TH treatment can be interrupted without danger to the developing central nervous system.⁴

TREATMENT

All infants with hypothyroidism should be rendered euthyroid as promptly as possible by thyroid hormone (L-T4) replacement therapy. An optimal TH therapy helps in optimal cognitive outcome. The goal of therapy is to normalize T4 within 2 weeks and TSH within 1 month. TSH levels should be maintained between 0.5 and 2.0 mU/L during the first 3 years of life.⁴⁻⁶

Administration of L-T4 is the treatment of choice. Although T3 is the more biologically active, most brain T3 is derived from local monodeiodination of T4, so T3 should not be used. The tablet should be crushed and suspended in a few milliliters of formula, breast milk, or water and taken empty stomach. Care should be taken to avoid concomitant administration of soy, fiber, or iron. Breastfeeding can continue.

The L-T4 dose should be adjusted according to the infant's clinical response and serum FT4 and TSH concentrations. During therapy, the serum total T4 or FT4 should and might be in the upper half of the reference range during the first 3 years of life with a low normal serum TSH.

FOLLOW-UP AND OUTCOME

Clinical evaluation of the infant by the practitioner should be conducted at frequent intervals during the first 3 years of age.

Infants need to undergo frequent laboratory and clinical evaluations of thyroid function, growth, and development to ensure optimal T4 dosage and adherence to their therapy regimen.⁵ Serum T4 and TSH measurements should be performed:

- At 2 and 4 weeks after the initiation of L-T4 treatment
- Every 1 to 2 months during the first 6 months of life
- Every 3 to 4 months between 6 months and 3 years
- Every 6 to 12 months until growth is completed; and at more frequent intervals when compliance is poor, abnormal values, or dose has been changed.
- FT4 and TSH measurements should be repeated 4 weeks after any change in dosage.

The outcome in infants with CH who are treated early is excellent. The prognosis for normal mental and neurologic performance is doubtful for those not detected early. Although physical recovery is good and stature is normal when replacement therapy is begun late 80 percent of infants given replacement therapy before 3 months of age have an IQ greater than 85, 77 percent of these infants show some signs of minimal brain damage, including impairment of arithmetic ability, speech, or fine motor coordination in later life^{7,8}. Long-term studies have shown that children with inadequate or delayed therapy also have cardiovascular morbidity in the form of left ventricular diastolic dysfunction, impaired exercise capacity, increased intima media thickness.

Key Point

- Universal screening of all newborns for CH is mandatory.
- The CH screening has a high benefit cost ratio.
- Either heel prick sample after 72 hours of life or cord blood can be used to perform TSH, T4 or both.
- Interpretation of results has to be done in relation to gestational age, age of life, presence of illness and established cut-offs.
- Early initiation of therapy to aim at normalizing T4 by 2 weeks and TSH by 4 weeks helps optimizing outcome.

CONGENITAL ADRENAL HYPERPLASIA

Congenital adrenal hyperplasia (CAH) is one of the common inborn errors of metabolism. It consists of a family of inherited disorders caused due to the loss or severely decreased activity of one of the five enzymes required for cortisol biosynthesis in the adrenal cortex (Flow chart 2). The various forms of CAH are due to mutations in the steroidogenic enzyme genes involved in cortisol biosynthesis. These enzymes are Desmolase, 3 β -hydroxysteroid dehydrogenase (*HSD3B2*), 21-hydroxylase (*CYP21*), 11- β -hydroxylase (*CYP11B1* and 2), 17 α -hydroxylase (*CYP17*).

Steroid 21-hydroxylase deficiency (21-OHD) is the most common enzymatic defect and accounts for more than 90 percent of cases of CAH. This autosomal recessive, monogenic, inherited defect of adrenal steroidogenic pathway results in inadequate corticosteroid production and excess of androgens. The phenotype is a manifestation of the degree of affection of glucocorticoid and mineralocorticoid synthesis and the presence of androgen excess. Thus, the phenotypic presentation can be one of salt wasters (SW) or nonsalt wasters (NSW) which can manifest as the severe classic (C) form or the milder nonclassic (NC) form depicting the residual enzyme activity.⁹ In females, androgen excess due to a severe defect causes prenatal virilization presenting as ambiguous genitalia at birth, the

this test, which remains the lowest of all screening conditions.^{13,14}

Compared with other newborn screening tests, the specificity of screening for CAH by immunoassay is low. Cross-reactivity of the specific antibody with other steroids, particularly pregnenolone, increases the number of false-positive results, which have been reported to be as high as 8 percent for different steroids and for several medications, greatly reducing discrimination between normal neonates and those with CAH.^{9,14} The 17OHP test shows a high false positive rate and it is difficult to interpret blood spot 17OHP levels because these values change with gestational age.

Despite the fact that CAH screening fulfills the WHO criteria for screening, it has not been universally included in NBS programs. This could be because, approximately 50 percent of CAH newborns are identified before the screening result is available (virilized CAH girls and patients with siblings with CAH) and the salt crisis may occur as early as 2 weeks of life. This emphasizes the need for rapid turnaround time (i.e. the result must be available before 10 days of life). Nevertheless, 50 percent of CAH infants (mainly boys) will get their diagnosis earlier by screening so that life-threatening salt crisis can be avoided. Furthermore, patients with milder variants of CAH may be detected early and precocious puberty and short stature can be avoided. In a recent review of CAH screening Brosnan et al concluded that published data clearly show that diagnosis can be made earlier by screening and serious salt crises can be avoided.¹⁵

It remains to be established that screening has a positive effect on mortality. Guidelines for neonatal CAH screening have recently been issued.

TREATMENT

Treatment is based on the principle of replacing normal glucocorticoid and mineralocorticoid needs, to suppress over secretion of adrenal androgens and to provide psychological support. Most female patients also need surgical reconstruction of the external genitalia.

The therapeutic dose of glucocorticoid and the type of glucocorticoid used are important. Ideally the replacement dose required is slightly higher than the endogenous cortisol secretion rate (6–8 mg/m²/day). In newly diagnosed patients and neonates the initial dose required might be much higher. Thus, the widely cited dose of 15 to 20 mg/m²/day of hydrocortisone is initiated but adjusted to the smallest dose that is able to normalize growth and physical maturation besides maintaining metabolic control. Oral hydrocortisone is the preferred glucocorticoid used and is given in three divided doses.

In SW patients' lifelong mineralocorticoid treatment is necessary, and additional salt supplements are needed to maintain plasma sodium concentration and renin in the

normal ranges during infancy. Salt supplementation (2–3 g/day) is given from birth to late childhood. Often, older children acquire a taste for salty food and do not require daily supplements of sodium chloride. Fludrocortisone in a dose of 0.1 to 0.2 mg/day as a single or two divided doses is recommended to maintain the salt balance. The doses may often be decreased after early infancy.¹⁰

Treatment of infants and children affected by the non-classic form of the disease is not recommended until and unless symptoms and signs of androgen excess become evident.

Adverse outcomes can occur in babies with false-positive results for CAH who receive treatment.

KEY POINTS

- Congenital adrenal hyperplasia (CAH) is a common inherited inborn error of metabolism leading to life-threatening crisis
- CAH screening helps identify infants at risk for the development of life-threatening adrenal crisis and to prevent the incorrect male sex assignment of affected female infants with ambiguous genitalia.
- Elevated levels of S-17-OHP adjusted for age, gestational age, weight, illness or stress helps diagnose CAH 21-OHD.
- Compared with other newborn screening tests, the specificity of screening for CAH by immunoassay is low and hence high false positive results.
- Additional steroid hormone assay and/or mutational studies besides CAH screening helps decrease the false positives.

Polycystic Ovary Syndrome in Adolescence

Ritu Jain, MP Jain

INTRODUCTION

Adolescence is a time of enormous physical and psychological change for young women. Polycystic ovary syndrome (PCOS) is the most common endocrine metabolic disorder affecting 11 to 26 percent of all adolescent girls¹ and has significant impact on quality of life and psychological morbidity. It has its origins in utero, seeds in adolescence, grows in reproductive phase and shadows the geriatrics. Polycystic ovary syndrome treatment not only needs multidisciplinary but multidimensional approach is required for the positive outcome.

Polycystic ovary syndrome is now a growing epidemic in developing countries because of changing life style and better nutrition patterns. The prevalence of overweight/obesity in urban children in Delhi has shown an increase from 16 percent in 2002 to about 24 percent in 2006.² The polycystic ovary syndrome (PCOS) in a teenager is characterized by irregular menstrual cycles, generally less than six menses per year, and by clinical or biochemical features of hyperandrogenism. More than 50 percent of PCOS patients have the metabolic syndrome

simultaneously, including obesity, insulin resistance and dyslipidemia.³

PCOS was first described by Stein and Leventhal in 1935, its definition has been readdressed several times. In 1990 the National Institutes of Health established new criteria, based on presence of hyperandrogenism and chronic anovulation with exclusion of other causes of hyperandrogenism such as congenital adrenal hyperplasia, hyperprolactinemia and androgen secreting neoplasms.⁴

The inclusion of ultrasound morphology of the ovaries as a further potential criteria to define PCOS was proposed by the Rotterdam Consensus Conference in 2003. This has suggested a broader definition for PCOS, with two of the three following criteria being diagnostic of this condition:

- Polycystic ovaries (either 12 or more peripheral follicles or increased ovarian volume (greater than 10 cm³) (Figs 1A and B)
- Oligo- or anovulation
- Clinical and/or biochemical signs of hyperandrogenism.

A raised luteinizing hormone/follicle-stimulating hormone ratio is no longer a diagnostic criteria.⁵

Figs 1A and B: Ultrasound showing: (A) Polycystic ovary and; (B) Hirsutism associated

More recently the Androgen Excess Society in 2006 (AES) has provided a contemporary version of the definition of PCOS and the fundamental role of hyperandrogenism has been pointed out. Both the NIH and the AES have declared hyperandrogenism as the core characteristic of PCOS.⁶ Considering the clinically evident association of hyperandrogenism with metabolic abnormalities, these two definitions fit better the metabolic phenotype of PCOS than Rotterdam Consensus. Conversely the Rotterdam criteria are less selective in metabolic terms, as they embrace a wider spectrum of women with less pronounced endocrine and metabolic abnormalities.⁷

A quarter of the world's adults are considered to have the metabolic syndrome and polycystic ovary is the female counterpart of it.⁸

ORIGINS

PCOS is a heterogeneous disorder which is believed to result from an interplay between genetic and epigenetic factors compounded by environmental triggers.

Genetics and PCOS

Earlier studies have suggested an autosomal dominant⁹ or X linked mode of inheritance,¹⁰ but the prevailing concept is that PCOS is a polygenic trait and female sub type of metabolic syndrome.¹¹ The rates of PCOS in mothers and sisters of patients with PCOS were 24% and 32%, respectively.¹²

The PCOS susceptibility genes/ loci so far can be divided into two broad groups: (1) Gene associated with sex hormone regulation and (2) genes associated with insulin resistance. Genes associated with sex hormones regulation are Fibrillin 3 (FBN3), Sex binding globulin (SHBG), X-linked androgen receptor (The AR Gene), Adrenal steroid 21-hydroxylase (CYP21), Dopamine D3 receptor and FSH-Beta. So far FBN3 gene shows strongest evidence for association to PCOS. Genes associated with insulin resistance are Caplin10 (CAPN10), Insulin-like growth factor 2 (IGF2), Insulin receptor substrates 1 and 2 (IRS1, IRS2).¹³

INSULIN RESISTANCE AND PCOS

Insulin receptor function is probably normal in women with PCOS. Abnormal serine phosphorylation is thought to be one of the major molecular pathways for insulin resistance in PCOS. If there is dysfunction of IRS-1, IRS-2 becomes active in presence of increased insulin concentration. This abnormal serine phosphorylation is involved in post-translational regulation of 17 to 20 lyase activity (CYP17). Thus, there may be a common etiology for both insulin resistance and hyperandrogenism. Polymorphic alleles of both IRS-1 and IRS-2, alone or in combination, may have functional impact on the insulin-resistant component of PCOS.¹⁴

HYPERANDROGENISM AND IN UTERO FETAL PROGRAMMING

The role of androgen exposure early in life adds to complexity to the heritability of PCOS. Androgen excess or increased GnRH release can produce the reproductive phenotype of PCOS.

Fetal programming of PCOS by androgen excess may be related to the phenomenon of sexually dimorphic programming of tissues leading toward more masculine phenotype with regard to reproductive, neuroendocrine and metabolic traits. PCOS is driven by an inherent hyperandrogenic activity of ovarian theca cells and male type pattern of pulsatile GnRH secretion which is due to fetal exposure to high androgens in utero.

Normally, the female fetus is protected in utero from maternal androgens by increased placental sex hormone binding globulin (SHBG) and placental Aromatase. SHBG binds the androgens and the placental aromatase converts them into estrogens. Excess maternal glucocorticoids (active cortisol) are converted by fetoplacental 11 β -hydroxysteroid dehydrogenase type 2, to inactive cortisone. Theoretically, therefore, exposure of female fetus to gestational hyperandrogenism may occur due to increased maternal or endogenous fetal androgen production and decreased placental SHBG or aromatase activity.

Pregnant PCOS women were found to have higher concentration of androgens, low SHBG and hyperinsulinemia, than normal pregnant women thus potentially exposing their daughters to elevated androgen levels in utero.¹⁵ Maternal hyperinsulinemia may induce excessive placental HCG production leading to fetal ovarian hyperplasia and hyperandrogenism.¹⁶ Maternal PCOS may lead to decreased nutrient supply to placenta and fetus by altering energy homeostasis and resulting growth retardation further leading to hyperinsulinemia and PCOS. These girls follow a path through postnatal catch up weight gain, amplified adrenarche, premature pubarche and ovarian hyperandrogenism in adolescence. In girls with premature pubarche persisting hyperandrogenism gets exacerbated by onset of gonadarche and PCOS during adolescence.¹⁷

Epigenetic abnormality hypothesis suggested by Zhongxiang Li and Hefeng Huang has established a novel mechanism for PCOS development and inheritance. It states that in utero hyperandrogenism exposure may disturb the epigenetic reprogramming in fetal reproductive tissue, thereby resulting in postnatal PCOS phenotype in women of reproductive age. Meanwhile, the incomplete erasure of such epigenetic abnormality in germ cells after fertilization may promote the transgenerational inheritance of PCOS.¹⁸

OBESITY—DIETARY FACTORS AND PCOS

Although insulin resistance is considered an inherent feature of PCOS, obesity is recognized as a significant aggravating factor associated in 30 to 70 percent.¹⁹ It is recognised that insulin resistance is less frequent in lean PCOS compared to their obese counterparts.²⁰

Visceral adiposity seems to be more important in lean PCOS than obesity *per se*. Interestingly, Lord et al have reported visceral adiposity is the most significant variable correlating with insulin resistance and metabolic dysfunction in PCOS.²¹ In view of the influential role of total and central obesity, diet emerges as an important factor in the perpetuation of insulin resistance in PCOS. Chronic over-nutrition is a widely acknowledged triggering factor of insulin resistance, particularly in susceptible individuals, like women with PCOS.²²

Currently, the quality of food and specifically, diet enriched to advanced glycated end products (AGEs) are incriminated in metabolic abnormalities via the increasing oxidative stress.²³ Increased AGEs levels positively correlate with serum androgen levels and with indices of insulin resistance in PCOS women.²⁴

Chronic exposure to high glycemic index food and free fatty acids cause beta cell dysfunction, increase TNF alpha and resistin and decrease insulin sensitizing agent, adiponectin further increasing insulin resistance.²⁵

PATHOPHYSIOLOGY OF PCOS

Insulin acts on classic insulin sensitive tissues like adipose tissue and skeletal muscle as well as nonclassic target tissue like ovary and endothelium. Insulin binding to its receptor cause phosphorylation of insulin receptor substrates (IRS) resulting in activation of mitogen activated kinase and phosphoinositide3-kinase (PI3K) signalling pathways. The multiplicity of signalling pathways downstream explains the pathway specific defects of insulin action in insulin resistance states.²⁶ A key feature of insulin resistance is that it is characterised by specific impairment in PI3K-dependent signalling pathways.²⁷

Autocrine, paracrine and hormonal factors modulate the coordination of theca and granulosa cell function in terms of androgen synthesis. Androgens and estrogens are negative modulators of LH effects whereas IGFs play a positive modulator role. Insulin also augments LH stimulated androgen production either via its own receptors or via IGF-1 receptors. In PCOS, the ovarian theca cells are increased in number, and they have increased steroidogenic capacity caused by increased transcription and mRNA stability of steroidogenic enzymes. Cystic follicles have high androstenedione to estradiol activity in contrast to healthy follicle where estradiol activity is higher in comparison to androstenedione. Also the granulosa cell fail to

increase the expression of aromatase leading to decreased estrogen secretion and prematurely express LH receptors and cholesterol side chain cleavage enzyme activity leading to over responsiveness to LH.

The ovary is considered as the main source of androgens in women with PCOS, although excess adrenal androgen production may occur. The enzymes used in formation of androstenedione from cholesterol is same in both, but under control of LH in ovary and ACTH in adrenal.²⁸

Insulin resistance increases endothelin-1, the most potent endothelial vasoconstrictor and marker of endothelial dysfunction, this explains the accelerated atherosclerosis in PCOS.²⁹

PCOS—A Chronic Inflammatory State

Several studies have unveiled the bidirectional relationship of insulin resistance with wide array of inflammatory/oxidative markers, including C-reactive protein, reactive oxygen species (ROS), Interleukin-18, protein carbonyls, soluble CD36, oxidised LDL and AGEs.³⁰

Beyond a simple association, there are data to support a casual, reciprocal relationship between inflammation/oxidative stress and insulin resistance in PCOS. The migration of macrophages in adipose tissue is a major proinflammatory process that is accentuated in presence of visceral obesity, which is present even in lean PCOS. Visceral adiposity, independent of obesity has been incriminated as a major trigger of insulin resistance and low grade chronic inflammation.³¹

Adiponectin, the most abundant adipokine mainly secreted from visceral adipocytes cells, has been found decreased in lean PCOS and obese women with PCOS, as compared with BMI matched controls. This aberration is caused by hyperinsulinemia. Adiponectin correlates negatively with progression of atherosclerosis. Other adipokines like resistin, retinol binding protein (RBP)-4, Visfatin are also implicated in PCOS.³² Visfatin is increased in both obese and lean PCOS and role of RBP-4 is unclear in human.³³

ENDOCRINE DISRUPTING CHEMICALS AND PCOS

Environmental endocrine disrupting chemicals also might disrupt ovarian and metabolic function, causing PCOS-like abnormalities. Bisphenol A (BPA), a widely used estrogenic industrial plasticizer, is one such endocrine disrupting chemical that is detectable in most individuals with PCOS.³⁴

Multivariate analysis confirmed that the risk factors associated with PCOS were disposable plastic cup for drinking, cooking oil fume and indoor decoration (P value: 0.011, 0.012, 0.026, 0.011, OR value: 2.800, 3.027, 2.370, 2.478).³⁵

CLINICAL PRESENTATION

PCOS symptoms usually develop gradually and start showing in early teens, when it is important for mother and pediatricians to be aware and watchful so that timely intervention can prevent progression of symptoms and long-term morbidity.

- Weight gain and upper body obesity (apple shaped) is more significant than weight gain near hips (pear-shaped). This visceral fat is linked to high androgen levels and more adverse metabolic risk profile than subcutaneous fat. Measurement of waist circumference is thought to correlate more closely with obesity risk than BMI.³⁶

One-third of PCOS are at high risk for development of metabolic syndrome.³⁷

According to the American Heart Association and the National Heart, Lung, and Blood Institute, metabolic syndrome is present if three or more of the following signs:

- Blood pressure equal to or higher than 130/85 mm Hg
- Fasting blood sugar (glucose) equal to or higher than 100 mg/dl
- Large waist circumference (length around the waist):
- Men—40 inches or more, Women—35 inches or more
- Low HDL cholesterol:
- Men—under 40 mg/dl, Women—under 50 mg/dl
- Triglycerides equal to or higher than 150 mg/dl

Hyperandrogenism

PCOS girls may present as hirsutism, acne, male pattern baldness, hair thinning, oily skin and acanthosis nigricans. Exaggerated signs of hyperandrogenism or virilisation suggest the work-up to rule out androgen producing tumor.

Hirsutism

The original method of Ferriman-Gallwey used 11 body areas to assess hair growth, but was decreased to 9 body areas in the modified method:

- Upper lip
- Chin
- Chest
- Upper back
- Lower back
- Upper abdomen
- Lower abdomen
- Upper arms
- Forearms (deleted in the modified method)
- Thighs
- Legs (deleted in the modified method)

In the modified method, hair growth is rated from 0 (no growth of terminal hair) to 4 (extensive hair growth) in each of the nine locations. A patient's score may therefore range from a minimum score of 0 to a maximum score of 36. A score of 8 or higher is regarded as indicative of androgen excess. Another proposed predictor of hirsutism is that terminal hair on the chin or the lower abdomen (Ferriman-Gallwey score ≥ 2) is nearly 100 percent sensitive and 27 percent specific at predicting total-body hirsutism.³⁸

Acanthosis nigricans is characterized by symmetrical, hyperpigmented, velvety plaques that may occur in almost any location but most commonly appear on the intertriginous areas of the axilla, groin, and posterior neck. The posterior neck is the most commonly affected site in children. Acrochordons (skin tags) are often found in and around the affected areas (Figs 2A and B).

Acanthosis nigricans is found in 5 percent of women with PCOS, is the hallmark if insulin resistance. A common mnemonic acronym for the clinical association of hyperandrogenism, insulin resistance, and acanthosis nigricans is the HAIR-AN syndrome.

Staging acanthosis (neck severity) is as follows:³⁹

- Absent (0): Not detectable on close inspection
- Present (1): Clearly present on close visual inspection, not visible to the casual observer; extent not measurable

Figs 2A and B: (A) Acanthosis nigricans and; (B) Acrochordons (For color version see plate 14)

- Mild (2): Limited to the base of the skull, usually does not extend to the lateral margins of the neck
- Moderate (3): Extends to lateral margins of neck, but not visible anteriorly
- Severe (4): Visible anteriorly
- Severe (5): Circumferential

Premature Adrenarche

It may be present in some population of adolescent girls. In 30 percent of peripubertal daughters of mothers with PCOS may be exaggerated adrenarche accompanied by higher serum DHEAS and insulin concentrations than age-matched and BMI-matched girls born to women without PCOS may represent a precursor to polycystic ovarian syndrome.⁴⁰ Both hirsutism and obesity may be present in premenarchal adolescent girls with polycystic ovarian syndrome.

Menstrual Abnormalities

The spectrum of irregular menses, estimated to be present in about 66 percent of adolescents with PCOS,⁴¹ includes primary or secondary amenorrhea, oligomenorrhea, anovulatory regular menses, and dysfunctional uterine bleeding with oligomenorrhea or menorrhagia. Menstrual disturbance is due to impaired oocyte developmental competence or anovulation and results in subfertility/infertility and increased miscarriages. In young girls precocious puberty may be the first manifestation.⁴²

Breathing Problems

While sleeping (obstructive sleep apnea). This is linked to both obesity and insulin resistance.

Psychological Morbidity

Obesity, hirsutism and acne may lead to poor self image and psychological difficulties. Poor body image can lead to depression and suicidal tendencies. Women with PCOS have an increased prevalence of mood disorders, including depression (26–40%), anxiety (11.6%) and binge-eating (23.3%).⁴³

- High blood pressure
- Prediabetes or in some cases, diabetes
- Asymptomatic PCOS (usually lean).

Important Assessment from Pediatrician Perspective⁴²

- History of PCOS in mother
- Postnatal catch up growth as assessed by available growth charts
- Early assessment of obesity by BMI, waist hip ratio (WHR)
- Watch out for early adrenarche, menarche and puberarche
- Signs of hyperandrogenism as acne, hirsutism, acanthosis nigricans
- Eating habits and physical activity
- Television and computer watching hours

DIAGNOSTIC EVALUATION

Girls with possible PCOS and other androgen excess disorders should undergo a relatively straightforward evaluation. Comprehensive assessment should be done according to PCOS performa which includes physical evaluation, lab investigations and follow-up schedule. Principal disorders to exclude are steroid 21-hydroxylase (*CYP21A2*) deficient nonclassic adrenal hyperplasia (NCAH), hyperprolactinemia and thyroid dysfunction.⁴⁴

- Serum (blood) levels of androgens including androstenedione and testosterone may be elevated. Dehydroepiandrosterone sulfate levels above 700 mcg/dl are highly suggestive of adrenal dysfunction because DHEA-S is made exclusively by the adrenal glands. The free testosterone level is thought to be the best measure, with ~60 percent of PCOS patients demonstrating supranormal levels. The Free androgen index of the ratio of testosterone to sex hormone-binding globulin (SHBG) is high, is meant to be a predictor of free testosterone, but is a poor parameter for this and is no better than testosterone alone as a marker for PCOS, possibly because FAI is correlated with the degree of obesity (Table 1).
- Hyperprolactinemia, mild and present in ~20 percent of women with PCOS.
- Thyroid dysfunction (hypothyroidism) by TSH levels.
- LH hypersecretion—elevated LH levels and an LH:FSH ratio >2:1 (or 3:1) initially thought to be essential for a diagnosis of the syndrome. However, single hormone measurements are now thought to be unreliable. LH sampling every 20 minutes over 6 hours gives a variability of 38 percent in the follicular phase and 92 percent in the luteal phase. LH hypersecretion is found in 40 percent of women with PCOS and is associated with a reduced chance of conception and increased risk of miscarriage. Additional tests for assessing comorbidity:
- Fasting biochemical screen and lipid profile
- 2-hour oral glucose tolerance test (GTT) in patients with risk factors (obesity, family history, history of gestational diabetes) may indicate impaired glucose tolerance (insulin resistance) in 15 to 30 percent of women with PCOS. Frank diabetes can be seen in 65 to 68 percent of women with this condition. Insulin resistance can be observed in both normal weight and overweight patients.
- Fasting insulin level or GTT with insulin levels (also called IGT). Elevated insulin levels have been helpful to predict response to medication and may indicate as who will need higher dosages of metformin or the use of a second medication to significantly lower insulin levels. Elevated blood sugar and insulin values do not predict who responds to an insulin-lowering medication, low-glycemic diet, and exercise. A hypoglycemic response in which the two-hour insulin level is higher and the blood sugar lower than fasting is consistent

Table 1: Laboratory tests for the evaluation of patients with suspected PCOS⁴⁴

<i>Laboratory test</i>	<i>Usefulness</i>
TSH	To rule out thyroid dysfunction and hyperprolactinemia if present, reassess for PCOS once resolved
Prolactin	
17-OHP (measured in the follicular phase)	If 17-OHP >6 nmol/l, perform an ACTH stimulation test. An ACTH-stimulated 17-OHP >10 nmol/l is diagnosis of 21-OH deficient NCAH*
Total and free testosterone	To assess for hyperandrogenemia if no clinical evidence of hyperandrogenism (that is, hirsutism) is present. Total testosterone >7 nmol/l or DHEAS >16 µmol/l should prompt evaluation for an androgen-secreting neoplasm; however, clinical presentation is more useful than androgen levels for predicting the presence of an androgen-secreting neoplasm
Luteal phase (day 22-24) progesterone	To assess ovulation in patients with hirsutism who 'report regular menses'
1 mg DST or 24 h urinary free cortisol	To screen for Cushing syndrome if clinical stigmata are present
*The ACTH stimulation test is performed with 250 mg of corticotropin, followed by measurement of 17-hydroxyprogesterone 60 min later.	
Abbreviations: ACTH, adrenocorticotrophic hormone; DHEAS, dehydroepiandrosterone sulfate; DST, dexamethasone suppression test; 21-OH, 21-hydroxylase; 17-OHP, 17-hydroxyprogesterone; NCAH, nonclassic adrenal hyperplasia; PCOS, polycystic ovary syndrome.	

with insulin resistance. A mathematical derivation known as the HOMAI, calculated from the fasting values in glucose and insulin concentrations, allows a direct and moderately accurate measure of insulin sensitivity (glucose-level x insulin-level/22.5).

LONG-TERM SEQUEL OF PCOS

PCOS has long-term reproductive morbidity, metabolic morbidity and predisposition to cancers:

- Increased incidence of multiple pregnancy following ovulation induction with perinatal mortality and morbidity
- Increased incidence of gestational diabetes (13% vs 5-10% in controls). Women should be screened before 20 weeks gestation and referred if abnormalities are detected.
- Increased incidence of pregnancy induced hypertension independent of obesity and gestational diabetes
- Sleep apnea is an independent cardiovascular risk factor and has been found to be more common in PCOS even after controlling for BMI. The strongest predictors for sleep apnea were fasting plasma insulin levels and glucose-to-insulin ratios. Sleep apnea is an independent risk factor for cardiovascular disease.
- Cardiovascular disease—mortality is not significantly increased although women with PCOS have abnormal lipid profiles. Offer measurement of fasting lipids as early detection of abnormal levels might prompt dietary change and exercise. Hypertension should be treated but conventional methods for estimating risk of cardiovascular disease have not been validated in women with PCOS.

- Increased risk of adult onset diabetes mellitus ~ 40 per cent risk of NIDDM by the age of 40 years with truncal obesity and a strong family history of NIDDM being additional risk factors. Women should be offered regular screening in the form of fasting glucose or GTT if additional risk factors (BMI > 30 or strong family Hx)⁴⁵
- Increased risk of endometrial cancer (5-fold), especially if interval between menses is greater than 3 months
- Risk of ovarian cancer in women with PCOS remains controversial but no additional surveillance is needed. Risk of breast cancer is not increased.

TREATMENT APPROACH

Treatment in PCOS should be individualized to treat prevailing signs and symptoms and is rarely monotherapeutic. Indications for treating PCOS include correcting metabolic dysfunction (with increased risks of T2DM and CVD), dermatological manifestations (hirsutism, acne or alopecia), anovulatory uterine bleeding (with increased risks of endometrial hyperplasia or carcinoma and anemia and/or anovulatory infertility, maintaining psychological health.

Main goal is to screen and diagnose early and prevent progression of symptoms to reduce its long-term consequences. It includes multidimensional approach and long-term follow-up.

Principles of treatment: Primary prevention is the best and starts at the hands of pediatrician.

- Life style management for life style disease
- Avoid stress, smoking and alcohol consumption
- Reduce and maintain weight.
- Modify diet.
- Regular exercise.

Secondary Prevention

- Metformin
- Weight reducing drugs
- Ovulation induction drugs

Tertiary Prevention

- Laparoscopy ovarian drilling
- Bariatric Surgery

The clinical management of young women with PCOS should be focused on her individual problems. Obesity worsens both symptomatology and the endocrine profile and so obese girls (BMI >25 kg/m²) should be encouraged to lose weight, and they should also have a test of fasting glucose tolerance (e.g. 2h GTT) and fasting insulin to assess the glucose:insulin ratio.

Encourage low glycemic diet (GI), as it improves insulin resistance and many of its metabolic consequences while high GI diet has been shown to worsen postprandial resistance.⁴⁶ A recent meta-analysis published in the Cochrane Database of Systemic Reviews supports the use of a low GI diet in weight management as 6 RCT have shown significant reductions in body mass, fat mass, body mass index, total mass index, total cholesterol and LDL cholesterol with it.⁴⁷ Diets higher in monosaturated and unsaturated fats are associated with reduced risk of cardiovascular diseases and type 2 diabetes.⁴⁸

Practical Dietary Advice for Girls with PCOS

- Choose oat-based cereals such as porridge or muesli
- Choose wholegrain breads in place of white/brown varieties
- Aim to fill half of plate at lunch/dinner with variety of vegetables or salad vegetables
- Include low GI grains in meals including barley, cracked wheat, quinoa and buck wheat.
- Snack on fresh fruit, raw nuts, yogurt and whole grain crackers
- Replace butter on bread with avocado, tahini or pure nut spreads
- Use olive or canola oil in cooking and olive oil or flax-seed oil in dressings
- Replace salt in cooking with fresh or dried herbs and spices.

Role of Exercise

In a randomized control trial investigating the effect of a 3 month exercise program in young woman with PCOS, a significant improvement in insulin sensitivity was observed in those who undertook three 30 min exercise sessions a week compared to sedentary controls.⁴⁹

Exercise Recommendations Based on American Diabetes Association (ADA):⁵⁰

- At least 150 min per week of moderate to high intensity exercise.
- Distribute exercise over 3 days with no more than two consecutive days without activity.
- Reduce sedentary activities (watching television and playing computer games) as much as possible.

HIRSUTISM IN POLYCYSTIC OVARY SYNDROME

A primary treatment for hirsutism in PCOS has not been established, and treatment is often palliative rather than curative. Agents that have been used include oral contraceptives, antiandrogen drugs (spironolactone, flutamide, finasteride), insulin-sensitizing agents, and eflornithine. The FDA has labeled only topical eflornithine hydrochloride cream for the treatment of hirsutism; additional benefits or risks for the use of this agent in women with PCOS are unknown.

Optimally treatment combines cosmetic and medical therapies. Medical therapy is aimed at slowing the rate of hair growth and is effective only after 6 to 9 months of therapy due to time of hair growth cycle whilst cosmetic treatments attempt to remove existing hair immediately. Cosmetic therapy may be waxing, bleach, or epilation as temporary measures or electrolysis and laser as permanent. Laser therapy works best in women with dark hair on fair skin, but is expensive and not permanent (despite claims to the contrary). Electrolysis is the only permanent method of hair removal and should be delayed until androgens are effectively suppressed.

Hyperandrogenism can be treated by a combination of an estrogen and CPA 50 mg. Estrogens lower circulating androgens by a combination of a slight inhibition of gonadotrophin secretion and gonadotrophin-sensitive ovarian steroid production and by an increase in hepatic production of sex hormone-binding globulin resulting in lower free testosterone, the preparation Dianette[®] (Schering, UK) contains ethinylestradiol in combination with CPA, although at a lower dose (2 mg). CPA acts as a competitive inhibitor at the androgen receptor. CPA can rarely cause liver damage and liver function should be checked after 6 months and then annually.

Spironolactone, a potassium sparing diuretic, has antiandrogenic properties and is useful in women for whom the oral contraceptive pill is contraindicated (e.g. because of hypertension). Spironolactone, at a dose of 50 ± 200 mg daily, may result in erratic menstrual bleeding and should be combined with reliable contraception.⁵¹

A new COCP, Yasmin[®] (Schering UK), contains the progestogen, drospirenone, which is a derivative of

spironolactone, with potential antiandrogenic properties and benefits for women with PCOS and those with anovulatory DUB.⁵²

Metformin Therapy for PCOS

Insulin resistance is often the first step in a progression to DM and CAD. Metformin has been the mainstay of treatment for IR and IGT in PCOS women over the past decade.

Mechanism of Action

- Metformin is a biguanide that acts principally on the liver to inhibit hepatic gluconeogenesis.
- It inhibits acetyl-CoA carboxylase activity and suppresses fatty acid production.
- Acts on skeletal muscle to inhibit lipid production and acts peripherally on adipose tissue to stimulate glucose transport and uptake.
- Reduces insulin levels and promotes improved insulin receptor activity.
- Has direct and indirect effects on the ovary with respect to insulin action and steroidogenic enzymatic activity.
- In the endothelium, metformin seems to improve nitric oxide vasodilatory effects.⁵³
- It does not cause hypoglycaemia.
- The most important side effect is gastrointestinal side effects. Sometimes other side effects are abdominal discomfort, diarrhoea, nausea, vomiting and decreased appetite, so it is started in incremental manner depending on tolerance.
- The most serious side effect is lactic acidosis, which is rare and almost always occurs in populations at high risk with renal insufficiency, liver disease and congestive heart failure.
- Early metformin therapy was found to prevent or delay the development of hirsutism, androgen excess, oligomenorrhea, and PCOS more effectively than late metformin. The time window of late childhood and early puberty may be more critical for the development and thus for the prevention, of adolescent PCOS than the first years beyond menarche.⁵⁴
- Metformin decreases androgen level significantly in both lean and obese individuals and restores ovulation and fertility.⁵⁵

Ovulation induction drugs, laparoscopic ovarian drilling are beyond scope of this chapter and not the treatment for adolescents.

CONCLUSION

PCOS is a not only a life style disease but life time disease which threatens the womanhood on reproductive, metabolic and oncology fronts. Proactive measures to screen and treat are needed in early adolescents to prevent transgenerational progression. Early metformin

therapy can break the vicious cycle of hyperinsulinemia and hyperandrogenemia. Most important is follow up of these girls and treatin the co-morbidities timely.

Diabetes Mellitus in Children: A Challenge Ahead

Neeraj Jain, Vibha Mangal Jain

Abstract

Diabetes mellitus (DM) is one of the ancient diseases. As early as 400 BC our Indian physician, Sushruta had described the disease as “Madhumeh”, the honey-urine disease. Type 1 diabetes is a continuing hormonal deficiency disorder that has significant short-term impacts on health and lifestyle and is associated with major long-term complications and reduced life expectancy. People with type 1 diabetes require insulin-replacement therapy from diagnosis to keep blood glucose concentrations as close as possible to the normal range to delay the long-term vascular complications of diabetes. Therefore, the complete treatment of diabetic patients not only includes meticulous attention to achievement of normoglycemia, but also correction of hypertension and dyslipidemia, correction of body weight and increase in physical activity. The goals of treating a child with DM are to achieve normal growth and development with prevention of acute and chronic complications of DM. These goals are achieved by coordinated care delivered by a multidisciplinary team focusing on insulin administration, glucose monitoring, meal planning, and screening for complications. Newer insulin analogues (“designer” insulin) and automated methods of delivery via programmable pumps have revolutionized the care of the child with diabetes. Systems of surveillance for the early detection of complications are important, as is effective management of complications when they occur.

INTRODUCTION

Diabetes mellitus is a metabolic syndrome characterized by chronic hyperglycemia with disturbance of carbohydrate, fat and protein metabolism resulting from improper insulin secretion and/or inefficient insulin action. This chronic hyperglycemia of diabetes is associated with long-term damage, dysfunction and failure of various organs especially the eyes, kidneys, nerves, heart and blood vessels. Insulin is produced by the beta cells of the islets of Langerhans located in the pancreas, and the absence, destruction, or other loss of these cells results in type 1 diabetes (insulin-dependent diabetes mellitus [IDDM]). Most children with diabetes have type 1 diabetes mellitus (T1DM) and a lifetime dependence on exogenous insulin.^{1,2}

INCIDENCE

According to recent WHO report the worldwide prevalence of diabetes is 135 million in 1995, which will increase to 300 million by the year 2025.^{3,4} India had 33 million diabetics in 2000, which will become 57

million in 2025. About 1.6 million cases are diagnosed every year in India. It is affecting the children as young as six. India has thus become the “Diabetic Capital of the World” India has the distinction of having the largest number of diabetics in the world.⁵ It is expected that 200 children under the age of 14 will develop the disease every day.⁶

Every year 70,000 children under the age of 15 develop type 1 diabetes worldwide. Incidence of type 1 diabetes is growing by 3 to 5 percent each year.⁷ In 2007, the five countries with the highest diabetes prevalence in the adult population are Nauru (30.7%), United Arab Emirates (19.5%), Saudi Arabia (16.7%), Bahrain (15.2%), and Kuwait (14.4%).⁸

There is a dramatic rise of diabetes in Asians and Pacific islanders. It is projected that 300 million people will be affected by 2025. China is predicted to have the highest rise in prevalence rate (68%) followed closely by India (59%) and other Asian countries (41%).⁹

Both types 1 and 2 diabetes can occur in children and adolescents (Table 1). Type 1 diabetes is the

most common chronic disease in children in the developed countries. Generally, incidence rates increase with age until mid puberty then decline after puberty, but type 1 DM can occur at any age. Children aged 1 to 4 years are particularly at risk and may die due to diabetic ketoacidosis (DKA) at the time of diagnosis. Adolescents are also a high-risk group.

Most deaths result from delayed diagnosis or neglected treatment and subsequent cerebral edema during treatment for DKA, although untreated hypoglycemia also causes some deaths. Unexplained death during sleep may also occur. One of the most common diseases found in children and teens is diabetes. Ninety to ninety-five percent of children with diabetes have type 1 diabetes. The other 5 to 10 percent have type 2.

Most of the time when a child is diagnosed with diabetes it is assumed to be type 1 but in the last 20 years type 2 diabetes has been on the rise in children and teenagers. Thousands of children a year are diagnosed with diabetes and health care providers keep finding that more and more of these children have type 2 diabetes.¹⁰

CAUSES

The exact cause of type 1 diabetes is unknown. Scientists do know that in most people with type 1 diabetes, the body's own immune system, which normally fights harmful bacteria and viruses by mistake destroys the insulin-producing (islet) cells in the pancreas. It is an autoimmune disease directed at the insulin-producing cells of the pancreatic islets of Langerhans. These cells are progressively destroyed; with insulin deficiency. Type 1 diabetes is characterized by autoimmune destruction of insulin-producing β cells in the pancreas by CD4+ and CD8+ T cells and macrophages infiltrating the islets.

Genetics may play a role in this process, and exposure to certain viruses may trigger the disease. Monozygotic twins have a 60 percent life time concordance for developing type 1 diabetes mellitus. In contrast, dizygotic twins have only an 8 percent risk of concordance, which is similar to the risk among other siblings. The frequency of diabetes developing in children with a diabetic mother is 2 to 3 percent and 5 to 6 percent if the father has type 1 diabetes mellitus. The risk in children rises to almost 30 percent if both parents are diabetic.¹¹

Human leukocyte antigen (HLA) class II molecules DR3 and DR4 are associated strongly with type 1 diabetes mellitus.¹² Patients expressing DR3 are also at risk for developing other autoimmune endocrinopathies and celiac disease. These patients are more likely to develop diabetes at a later age. Patients expressing DR4 are usually younger at diagnosis and more likely to have positive insulin antibodies, yet they are unlikely to have other autoimmune endocrinopathies.

Two combinations of HLA genes (or haplotypes) are of particular importance: DR4-DQ8 and DR3-DQ2 are present in 90 percent of children with type 1 diabetes. A third haplotype, DR15-DQ6, is found in less than 1 percent of children with type 1 diabetes, compared with more than 20 percent of the general population, and is considered to be protective. The genotype combining the 2 susceptibility haplotypes (DR4-DQ8/DR3-DQ2) contributes the greatest risk of the disease and is most common in children in whom the disease develops very early in life. First-degree relatives of these children are themselves at greater risk of type 1 diabetes than are the relatives of children in whom the disease develops later.

Candidate gene studies also identified the insulin gene on chromosome 11 as the second most important genetic susceptibility factor, contributing 10 percent of genetic susceptibility to type 1 diabetes. Shorter forms of a variable number tandem repeat in the insulin promoter are associated with susceptibility to the disease, whereas longer forms are associated with protection. Demonstration of increased expression of insulin (mRNA) in the thymus of people with "long" or protective repeats—which suggests more efficient deletion of insulin-specific T cells during induction of central tolerance—provides an attractive potential mechanism for the role of the insulin gene in type 1 diabetes.

Over the last decade, whole genome screens have indicated that there are at least 15 other loci associated with type 1 diabetes, 16 to 18 and of those, another 2 genes intimately associated with T cell activation have been identified recently. An allele of the gene for a negative regulator of T cell activation, cytotoxic T lymphocyte antigen 4 (*CTLA-4*), found on chromosome 2q33, is considered to be the third susceptibility locus for type 1 diabetes and has been associated with increased levels of soluble *CTLA-4* and the frequency of regulatory T cells. A variant of *PTPN22*, the gene encoding LYP, also a suppressor of T cell activation, has been deemed the fourth susceptibility factor. The observation that the 4 most important susceptibility genes for type 1 diabetes can all be represented on a single diagram of antigen presentation to T cells (emphasizes the potential importance of current therapeutic strategies targeting this interaction). It is also worth noting that the HLA, *CTLA-4* and *PTPN22* have all been implicated in autoimmune thyroid disease and other autoimmune diseases, which supports the premise that similar or overlapping biological pathways contribute to different autoimmune diseases.¹²⁻¹⁴

No single factor has been identified, but infections and diet are considered the two most likely environmental candidates. Viral infections may be the most important environmental factor in the development of type 1 diabetes mellitus, probably by initiating or modifying an autoimmune process.¹⁵ Instances have been reported of a direct toxic effect of infection in congenital rubella.

Dietary factors are also relevant. Breastfed infants have a lower risk for IDDM, and a direct relationship is observed between per capita cow's milk consumption and the incidence of diabetes. Some cow's milk proteins (e.g. bovine serum albumin) have antigenic similarities to an islet cell antigen.

Nitrosamines, chemicals found in smoked foods and some water supplies, are known to cause type 1 diabetes mellitus in animal models; however, no definite link has been made with humans. Reduced exposure to UV light and lower vitamin D levels, both of which are more likely found in the higher latitudes, are associated with an increased risk of type 1 diabetes mellitus. Chemical causes: Streptozotocin and RH-787, a rat poison, selectively damage islet cells and can cause type 1 diabetes mellitus.^{16,17}

The cause of type 1 diabetes is different from the more common type 2 diabetes. In type 2, the islet cells are still functioning, but the body becomes resistant to insulin or the pancreas does not produce enough insulin. The environmental factors may interact with a genetically susceptible person.

Other causes are:

- Congenital absence of the pancreas or islet cells
- Pancreatectomy
- Type 1 diabetes mellitus secondary to pancreatic damage (i.e. cystic fibrosis, chronic pancreatitis, thalassemia major, hemochromatosis, hemolytic-uremic syndrome)
- Wolfram syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, deafness [DIDMOAD])
- Chromosomal disorders such as down syndrome, turner syndrome, klinefelter syndrome, or Prader-Willi syndrome (The risk is said to be around 1 percent in down and turner syndromes).

CLINICAL MANIFESTATION

The American Diabetes Association's (ADAs) criteria for the diagnosis of DM were recently revised to include a new threshold for the diagnosis of impaired glucose tolerance (IGT) and impaired fasting glucose (IFG).

The diagnosis of DM is made on the basis of one of the following criteria:

- Symptoms of hyperglycemia including polyuria, polydipsia, weight loss plus random plasma glucose concentration >200 mg/dl (11 mm).
- Fasting (>8 hr fast) plasma glucose >126 mg/dl (7 mm).
- 2 hr postprandial glucose >200 mg/dl during an oral glucose tolerance test (OGTT).

Criteria for diagnosing IGT and IFG are two hours plasma glucose between 140 to 200 mg/dl or a fasting glucose between 100 to 125 mg/dl respectively.

The ADA classification of DM encompasses 4 groups: Type 1, Type 2, other specific types of diabetes, and

gestational diabetes. Type 1 DM is further subclassified into Type 1A which is associated with the presence of islet cell autoantibodies, and Type 1B characterized by the absence of such antibodies. Advances in our understanding of the physiology, and molecular and cellular basis for insulin secretion and action have prompted the continued evolution of alternate classifications.^{18,19}

- Diabetes with predominantly insulin deficiency including T1DM, neonatal diabetes, maturity onset diabetes of the young, and mitochondrial diabetes.
- Diabetes and other syndromes with predominantly insulin resistance, e.g. leprechaunism, lipodystrophic diabetes, and other entities where the resistance cannot usually be overcome by even supraphysiological insulin concentrations.
- Diabetes resulting from combined insulin deficiency and insulin resistance: T2DM. In normal physiology, the product of insulin secretion and insulin sensitivity is a constant, such that insulin resistance is compensated by increased insulin secretion and vice versa. Clinical diabetes only occurs when the product cannot be maintained within normal limits, usually because insulin secretion is inadequate to compensate for the prevailing degree of resistance to insulin action.²⁰

The most easily recognized symptoms of type 1 diabetes mellitus (T1DM) are secondary to hyperglycemia, glycosuria, and diabetic ketoacidosis (DKA). Their symptoms may include the following:

- Severe monilial diaper/napkin rash
- Unexplained malaise
- Poor weight gain or weight loss
- Increased thirst
- Vomiting and dehydration, with a constantly wet napkin/diaper

Hyperglycemia

Hyperglycemia alone may not cause obvious symptoms, although some children report general malaise, headache, and weakness.

They may also appear irritable and become ill-tempered. The main symptoms of hyperglycemia are secondary to osmotic diuresis and glycosuria.

Glycosuria

This condition leads to increased urinary frequency and volume (e.g. polyuria), which is particularly troublesome at night (e.g. nocturia) and often leads to enuresis in a previously continent child. These symptoms are easy to overlook in infants because of their naturally high fluid intake and diaper/napkin use.

Polydipsia

Increased thirst, which may be insatiable, is secondary to the osmotic diuresis causing dehydration.

Weight Loss

Insulin deficiency leads to uninhibited gluconeogenesis, causing breakdown of protein and fat. Weight loss may be dramatic, although the child's appetite usually remains good.

Failure to thrive and wasting may be the first symptoms noted in an infant or toddler and may precede frank hyperglycemia.

Nonspecific Malaise

Although this condition may be present before symptoms of hyperglycemia, or as a separate symptom of hyperglycemia, it is often only retrospectively recognized.

Symptoms of Ketoacidosis

Severe dehydration, smell of ketones, acidotic breathing (i.e. Kussmaul respiration), masquerading as respiratory distress, abdominal pain, vomiting drowsiness and coma.

Other nonspecific findings

Hyperglycemia impairs immunity and renders a child more susceptible to recurrent infection, particularly of the urinary tract, skin, and respiratory tract. Candidiasis may develop, especially in groin and flexural areas.

A physical examination may reveal findings associated with other autoimmune endocrinopathies, which have a higher incidence in children with type 1 diabetes mellitus (e.g. thyroid disease with symptoms of overactivity or underactivity and possibly a palpable goiter). Cataracts are rarely presenting problems and typically occur in girls with a long prodrome of mild hyperglycemia.

Necrobiosis lipoidica usually, but not exclusively, occurs in people with diabetes. Necrobiosis most often develops on the front of the lower leg as a well-demarcated, red atrophic area. The condition is associated with injury to dermal collagen, granulomatous inflammation, and ulceration. The cause of necrobiosis is unknown, and the condition is difficult to manage. It is also associated with poor metabolic control and a greater risk of developing other diabetes-related complications.^{21,22}

Dawn phenomenon

Blood glucose levels tend to rise in the early hours of the morning (usually after 0500 hours) prior to waking. This is called the dawn phenomenon. In nondiabetic individuals the mechanisms include increased nocturnal growth hormone secretion, increased resistance to insulin action and increased hepatic glucose production. These mechanisms are more potent in puberty.

Somogyi phenomenon is rebound hyperglycemia after hypoglycemia, which may be asymptomatic. This is caused by release of counter-regulatory hormones (e.g. catecholamines, cortisol, glucagon, growth hormone) in response to hypoglycemia.

SECONDARY DIABETES

This subclass contains a variety of types of diabetes, for some of which the etiologic relationship is known. Examples include diabetes secondary to exocrine pancreatic diseases, such as cystic fibrosis; endocrine diseases other than pancreatic diseases (e.g. Cushing syndrome); and ingestion of certain drugs or poisons (e.g. the rodenticide Vacor). Certain genetic syndromes, including those with abnormalities of the insulin receptor; also are included in this category. There are no associations with HLA's, autoimmunity, or islet cell antibodies among the entities in this subdivision.

Transient Diabetes Mellitus of the Newborn

Onset of persistent insulin-dependent diabetes before the age of 6 months is very unusual. The syndrome of transient diabetes mellitus in the newborn infant has its onset in the first weeks of life and persists only several weeks to months before resolving spontaneously. It occurs most often in infants who are small for gestational age and is characterized by hyperglycemia and pronounced glycosuria, resulting in severe dehydration and at times metabolic acidosis but with only minimal or no ketonemia or ketonuria. Insulin responses to glucose or tolbutamide are low to absent; basal plasma insulin concentrations, however, are normal. After spontaneous recovery, the insulin responses

Table 1: Characteristics of type 1 and type 2 diabetes in children and adolescents

Characteristic	Type 1	Type 2	Mody
Age at onset	Throughout childhood	Pubertal	Pubertal
Gender	Female = Male	Female > Male	Female = Male
Ethnicity	All (low incidence in Asians)	Native American African American	Caucasian Hispanic
Onset	Acute severe DKA common	Insidious ketosis less common	Gradual
Obesity	As in population	Common	Uncommon
Acanthosis nigricans	Absent	Present	Absent
Insulin secretion	Decreased/absent	Variable	Variably decreased

to these same stimuli are brisk and normal, implying a functional delay in β -cell maturation with spontaneous resolution. Occurrence of the syndrome in consecutive siblings has been reported. Permanent diabetes does not usually develop, although there are reports of patients with classic type I diabetes who formerly had transient diabetes of the newborn. It remains to be determined whether this association of transient diabetes in the newborn followed much later in life by classical IDDM is a chance occurrence or causally related. This syndrome should be distinguished from severe hyperglycemia that may occur in hypertonic dehydration, this occurs usually in infants past the newborn period, who respond promptly to rehydration and have a minimal requirement for insulin.

Administration of insulin is mandatory during the active phase of this syndrome. Intermediate-acting insulin in the dose of 1 to 2 U/kg/24 hr given in two divided doses, usually results in dramatic improvement and accelerated growth and gain in weight. Attempts at gradually reducing the dose of insulin may be made as soon as recurrent hypoglycemia becomes manifest or after 2 months of age. The parents should be assured of the transient nature of the disease and the excellent prognosis. Rarely, pancreatic agenesis may be associated with early but permanent diabetes mellitus as well as malabsorption.

The complications of type 1 diabetes mellitus ²²⁻²⁵

- Can be divided into three major categories:
 - Acute complications include: hypoglycemia, hyperglycemia, and DKA.²⁶
 - Long-term complications include the following:
 - Retinopathy
 - Cataracts
 - Hypertension
 - Progressive renal failure
 - Early coronary artery disease
 - Peripheral vascular disease
 - Neuropathy, both peripheral and autonomic
 - Increased risk of infection.
- Associated autoimmune diseases are common with type 1 diabetes mellitus, particularly in children who have the human leukocyte antigen DR3 (HLA-DR3). Some conditions may precede development of diabetes; others may develop later. As many as 20 percent of children with diabetes have thyroid autoantibodies.

LABORATORY STUDIES

Random Blood Sugar Test

A blood sample can be taken at a random time. Blood sugar values are expressed in milligrams per deciliter (mg/dl) or millimoles per liter (mmol/L). Regardless of when your child last ate, a random blood sugar level of 200 mg/dl (11.1 mmol/L) or higher suggests diabetes.

Fasting Blood Sugar Test

A blood sample can be taken after an overnight fast. A fasting blood sugar level less than 100 mg/dl (5.6 mmol/L) is normal. A fasting blood sugar level from 100 to 125 mg/dl (5.6–6.9 mmol/L) is considered prediabetes. If it is 126 mg/dl (7 mmol/L) or higher on two separate tests, your child will be diagnosed with diabetes.

Glycosylated Hemoglobin (A₁C) Test

This blood test indicates an average blood sugar level for the past two to three months. It works by measuring the percentage of blood sugar attached to hemoglobin, the oxygen-carrying protein in red blood cells. The higher the blood sugar levels, the more hemoglobin that has sugar attached. An A₁C level of 6.5 percent or higher on two separate tests indicates diabetes.

Glucose Tolerance Test

If the diagnosis is still unclear from these tests, a glucose tolerance test can be carried out. A glucose drink is given containing a standard amount of glucose (75g). Blood samples are taken before the drink is given and two hours later. The test is done after an overnight fast. A two-hour blood glucose level above 11.1 mmol/L is a diagnostic of diabetes. A level below 7.8 mmol/L is normal. If the level falls between these values, it suggests a decreased tolerance for glucose. This is known as impaired glucose tolerance (IGT).

Urine

A positive urine glucose test suggests, but is not diagnostic for, type 1 diabetes mellitus (T1DM). Diagnosis must be confirmed by test results showing elevated blood glucose levels. Test urine of ambulatory patients for ketones at the time of diagnosis. Ketones in the urine confirm lipolysis and gluconeogenesis, which are normal during periods of starvation. With hyperglycemia and heavy glycosuria, ketonuria is a marker of insulin deficiency and potential DKA.

Beginning at age 12 years, perform an annual urinalysis to test for a slightly increased AER, referred to as microalbuminuria, which is an indicator of risk for diabetic nephropathy.

Liver and Renal Function Tests

The liver helps maintain normal blood glucose concentration in the fasting and postprandial states. Loss of insulin effect on the liver leads to glycogenolysis and an increase in hepatic glucose production. Abnormalities of triglyceride storage and lipolysis in insulin-sensitive tissue's such as the liver are an early manifestation of conditions characterized by insulin resistance and are detectable earlier than fasting hyperglycemia. The precise genetic, environmental, and metabolic factors and sequence of events that

lead to the underlying insulin resistance, however, is not fully understood.

Diabetes is the leading cause of chronic kidney failure, or end-stage renal disease (ESRD). Uncontrolled high glucose levels can damage the nephrons. Measurement of serum creatinine is a screening test for diabetic nephropathy. All patients with diabetes should have their serum creatinine measured at diagnosis and at regular intervals thereafter, usually annually. Microalbuminuria rarely occurs with short duration of type 1 diabetes; therefore, screening in individuals with type 1 diabetes should begin after 5 years' disease duration.

Thyroid Function Tests

Because early hypothyroidism has few easily identifiable clinical signs in children, children with type 1 diabetes mellitus may have undiagnosed thyroid disease. Untreated thyroid disease may interfere with diabetes management. Check thyroid function regularly (every 2 to 5 years or annually if thyroid antibodies are present). Antithyroid antibody tests indicate the risk of present or potential thyroid disease.

Antigliadin Antibodies

Some children with type 1 diabetes mellitus may have or may develop celiac disease. Positive antigliadin antibodies, especially specific antibodies (e.g. antiendomysial, antitransglutaminase) are important risk markers. If antibody tests are positive, a jejunal biopsy is required to confirm or refute a diagnosis of celiac disease.

Lipid Profile

Lipid profiles are usually abnormal at diagnosis because of increased circulating triglycerides caused by gluconeogenesis. Apart from hypertriglyceridemia, primary lipid disorders rarely result in diabetes. Hyperlipidemia with poor metabolic control is common.

C-peptide Assay

Beta cells produce insulin and C-peptide in a 1:1 ratio. High blood sugar in the presence of C-peptide usually means a person is insulin resistant or type 2 diabetes. High blood sugar with a low or undetectable level of C-peptide means a person is insulin deficient or type 1. C-peptide actually causes insulin resistance by impairing the cells of the body from taking up more glucose. Physiologically this is because the blood sugar in the body is more than the body can handle. The idea is to prevent the insulin resistance from occurring in the first place. This can be done by increasing energy demands of the body through exercise or eating less refined and processed carbohydrates—resulting in less insulin secretion and less C-peptide.

The presence of anti-islet antibodies (to Glutamic Acid Decarboxylase, Insulinoma Associated Peptide-2 or

insulin)- American Diabetes Association expert committee has proposed an etiologic classification of diabetes with type 1A diabetes representing immune-mediated diabetes and type 1B a nonautoimmune idiopathic form of type 1 diabetes. Additional diseases with severe β -cell deficiency with known genetic or environmental etiologies are categorized individually. The best current markers to distinguish type 1A diabetes from other forms of diabetes are the presence of anti-islet autoantibodies. Typically, autoantibodies reacting with glutamic acid decarboxylase (GAD65), insulin, and insulinoma antigen-2 are measured. Assays can be set such that each assay has a false-positive rate of approximately 1 percent, and together one or more of these autoantibodies are present in approximately 90 percent of new onset patients with type 1A diabetes. There are undoubtedly additional autoantigens to be defined, and a subset of patients lacking the above three islet autoantibodies express cytoplasmic islet cell autoantibodies measured with indirect immunofluorescent staining of human pancreas. This latter assay has however a long history of poor standardization and although it detects a subset of GAD65 and insulinoma antigen-2 autoantibodies, it does not detect anti-insulin autoantibodies. Testing for GAD 65 antibodies has been proposed as an improved test for differentiating between Type 1 and Type 2 Diabetes. Islet cell antibodies may be present at diagnosis but are not needed to diagnose type 1 diabetes mellitus. Islet cell antibodies are nonspecific markers of autoimmune disease of the pancreas and have been found in as many as 5 percent of unaffected children. Other autoantibody markers of type 1 diabetes are known, including insulin antibodies. Additional antibodies against islet cells are recognized (e.g. those against glutamate decarboxylase [GAD antibodies]), but these are generally unavailable for routine testing.

TREATMENT

The initial step after the diagnosis is made is life-style modification. The patient is advised an appropriate diet and suitable exercise program. The response to diet and exercise should be assessed for two months in general.

DIET

The following are among the most recent consensus recommendations:

- Carbohydrates should provide 50 to 55 percent of daily energy intake (No more than 10 percent of carbohydrates should be from sucrose or other refined carbohydrates).
- Fat should provide 30 to 35 percent of daily energy intake.
- Protein should provide 10 to 15 percent of daily energy intake.
- View these recommendations in the patient's cultural context.

- Adequate intake of complex carbohydrates (e.g. cereals) is important before bedtime to avoid nocturnal hypoglycemia, especially for children having twice-daily injections of mixed insulin.
- The dietician should develop a diet plan for each child to suit individual needs and circumstances. Regularly review and adjust the plan to accommodate the patient's growth and lifestyle changes.
- Low-carbohydrate diets as a management option for diabetes control have regained popularity in recent years. Logic dictates that the lower the carbohydrate intake, the less insulin is required. No trials of low-carbohydrate diets in children with type 1 diabetes mellitus have been reported, and such diets cannot be recommended at the present.

Activity

- *Type 1 diabetes mellitus*: Exercise has real benefits for a child with diabetes. Most children can adjust their insulin dosage and diet to cope with all forms of exercise.
- *Role of yoga*: Several well-planned studies have demonstrated the beneficial effects of yogic practices in diabetics. Some of the asanas that were found to produce these benefits are *Dhanurasana*, *Ardhamatsayendrasana*, *Bhujangasana*, *Naukasana*, *Halasana*, *Paschimotasana*, and *Shavasana pranayam*.

Insulin

- Insulin is always required to treat type 1 diabetes mellitus. Originally, all insulin was derived from the highly purified pancreatic extracts of pigs and cattle, and this form of insulin is still available. Human insulin was later manufactured using recombinant DNA technology (Table 2).
- More recently, “designer” insulin's are produced based on the human molecule and are tailored to meet

specific pharmacological targets, particularly duration of action. Insulin must be given parenterally and this effectively means subcutaneous injection.

- Type 1 is treated with insulin replacement therapy—usually by insulin injection or insulin pump, along with attention to dietary management, typically including carbohydrate tracking, and careful monitoring of blood glucose levels using glucose meters.
- Insulin has four basic formulations—ultra short-acting (e.g. lispro, aspart, glulisine) traditional short-acting (e.g. regular, soluble), medium-acting or intermediate-acting (e.g. isophane, lente, detemir), and long-acting (e.g. ultralente, glargine).
- Regular or soluble insulin is bound to either protamine (e.g. isophane) or zinc (e.g. lente, ultralente) in order to prolong the duration of action. Combinations of isophane and regular, lispro or aspart insulins are also available in a limited number of concentrations that vary around the world, ranging from 25:75 mixtures to 50:50 mixtures.

Injection Regimens

- Twice-daily combinations of short-acting and intermediate-acting insulin.
- Multiple injection regimens, using once-daily or twice-daily injections of long-acting or intermediate-acting insulin and short-acting insulins given at each meal.
- A combination of the above two regimens, with a morning injection of mixed insulin, an afternoon pre-meal injection of short-acting insulin and an evening injection of intermediate-acting or long-acting insulin.
- Continuous subcutaneous insulin infusion (CSII) using an insulin pump.
- A wide variety of insulin-injection devices are available, including a simple syringe and needle, semiautomatic

Table 2: Timing of action of available insulins

	Insulin onset (hour) <i>Lispro 0.25</i>	Peak (hour) <i>0.5–1.0</i>	Duration (hour) <i>3</i>
<i>Regular</i>			
Human	0.5–1.0	2–3	3–6
Pork	0.5–2.0	3–4	4–6
<i>NPH/Lente</i>			
Human	2–4	4–10	10–16
Pork	4–6	8–14	16–20
<i>Ultralente</i>			
Human	6–10	Minimal (?)	18–20
Animal	8–14	Minimal	24–36
<i>Mixed (70% NPH, 30% regular)</i>			
Human	0.5	2–12	24

pen injector devices, and needle-free jet injectors. Increasing numbers of young people use insulin pumps to deliver continuous subcutaneous insulin, with bolus doses at meal times.

- When prescribing tailor the insulin dose to the individual child's needs. For instance, if using a twice-daily regimen, then, as a rule of thumb, prepubertal children require between 0.5 and 1 U/kg/d, with between 60 to 70 percent administered in the morning and 30 to 40 percent in the evening.
- Insulin resistance is a feature of puberty, and some adolescents may require as much as 2 U/kg/d. About one-third of the administered insulin is a short-acting formulation and the remainder is a medium-acting to long-acting formulation.
- Basal bolus regimens have a higher proportion of short-acting insulin. Typically, 50 percent of the total daily dose is given as long-acting or intermediate-acting insulin. CSII uses only short-acting insulin's, most often the analogues lispro or aspart. Typically, they also have around 50 percent of the insulin given at a basal rate; the remainder is given as food-related boluses.
- Alternatives to injecting insulin have been constantly sought; the most recent is an inhaled form of insulin. The search for alternatives continues, including oral sprays, sublingual lozenges, and delayed-absorption capsules.

Most children and adolescents require at least two injections per day of short and intermediate-acting insulin to achieve satisfactory metabolic control; the injections are administered shortly before breakfast and dinner. During the honeymoon period, when insulin requirements are at a minimum, one injection per day may be satisfactory for control. Except for this period, achieving control with a single daily injection is nearly impossible. Absorption may vary from different injection sites and is more rapid in exercised sites and at higher temperatures. Injection into hypertrophied sites may slow absorption.

Frequent blood glucose monitoring is necessary so that patients can respond to the levels by adjusting their insulin doses. For example, if an occasional fasting blood glucose level falls above the target range, the morning short-acting insulin dose should be increased. If the fasting blood glucose level is increased for several consecutive days, the evening NPH dose should be increased.

During the honeymoon period, dose requirements may drop to less than 0.5 U/kg/day. Except during this period, most preadolescent children need approximately 0.75 to 1.00 U/kg/day. Teenagers usually require approximately 1.0 to 1.2 U/kg/day after the first few years of the disease.

Patients on a twice-daily dosage regimen typically need approximately two-thirds of the total dose in the

morning and one-third before dinner. The doses usually are split between one-third short-acting (regular or lispro) and two-thirds NPH to one-half short-acting and one-half NPH. More short-acting insulin usually is required in the morning because of an early morning glucose rise. This early morning glucose increase (i.e. dawn phenomenon) may be caused by normal nocturnal increases in some counter-regulatory hormones.

Other insulin regimens may be needed to achieve adequate control. Often, the evening dose must be separated, with short-acting insulin given before dinner and NPH at bedtime to maintain adequate insulin levels throughout the entire night and to avoid hypoglycemia during the hours between 1:00 and 4:00 am. Sometimes additional short-acting insulin is needed before lunch, although this may be difficult to arrange in a school-aged child (without interfering with his or her school schedule), or before a mid afternoon snack.

Ultralente can be used to provide a continuous, fairly steady insulin level with a once or twice-daily dose, with short-acting insulin given before each meal. The use of continuous subcutaneous insulin infusion pumps can be considered in highly motivated and conscientious patients. Short-acting insulin is used for continuous subcutaneous infusion to achieve a continuous basal rate, with bolus doses given before meals. In other words, many different regimens are available. When insulin doses are more than 1.5 U/kg/day and especially when they are at or more than 2 U/kg/day, overtreatment must be considered. Excess insulin doses can worsen control and produce a clinical picture of widely variable blood glucose values.

New approaches for treatment:

- Pancreas transplantation
- Islet cell transplantation
- Stem cells approach
- Gene therapy approach

Alternatives to injecting insulin have been constantly sought; the most recent is an inhaled form of insulin. Several products were in development, and one (Exubera) was licensed for use but failed to generate sufficient market penetration to justify continued production. The search for alternatives continues, including oral sprays, sublingual lozenges, and delayed-absorption capsules.

Pancreas Transplantation

Pancreas transplants are generally performed together with or sometime after a kidney transplant. One reason for this is that introducing a new kidney requires taking immunosuppressive drugs such as cyclosporin. Nevertheless this allows the introduction of a new, functioning pancreas to a patient with diabetes without any additional immunosuppressive therapy. However, pancreas transplants alone can be wise in patients with extremely labile type 1 diabetes mellitus.

Scientists have found another alternative mode of pancreas transplantation through the use of xenografts especially from animals such as pigs. This alternative mode of transplantation from animals provides an alternative therapy for the treatment of type 1 diabetes.

Islet Cell Transplantation

Islet cell transplantation is expected to be less invasive than a pancreas transplant which is currently the most commonly used approach in humans.

Stem Cells Approach

Research is being done at several locations in which islet cells are developed from stem cells.

Gene Therapy Approach

Designing a viral vector to deliberately infect cells with DNA to carry on the viral production of insulin in response to the blood sugar level. Technology for gene therapy is advancing rapidly such that there are multiple pathways possible to support endocrine function, with potential to practically cure diabetes.

PREVENTION

New approaches are:

- Immunization approach
- DiaPep277
- Intranasal insulin
- Bacillus Calmette Guérin research
- Diamyd

Immunization Approach

If a biochemical mechanism can be found that prevents the immune system from attacking beta cells, it may be administered to prevent commencement of diabetes type 1. Several groups are trying to achieve this by causing the activation state of the immune system to change from Th1 state ("attack" by killer T Cells) to Th2 state (development of new antibodies). This Th1-Th2 shift occurs via a change in the type of cytokine signalling molecules being released by regulatory T cells. Instead of proinflammatory cytokines, the regulatory T cells begin to release cytokines that inhibit inflammation. This phenomenon is commonly known as "acquired immune tolerance".

DiaPep277

A substance designed to cause lymphocyte cells to cease attacking beta cells, DiaPep277 is a peptide fragment of a larger protein called HSP60. Given as a subcutaneous injection, its mechanism of action involves a Th1-Th2 shift. Clinical success has been demonstrated in prolonging the "honeymoon" period for people who already have

type 1 diabetes. The product is currently being tested in people with latent autoimmune diabetes of adults (LADA).

Intranasal Insulin

There is preclinical evidence that a Th1-Th2 shift can be induced by administration of insulin directly onto the immune tissue in the nasal cavity. This observation has led to a clinical trial, called INIT II, which began in late 2006, based in Australia and New Zealand.

Bacillus Calmette-Guérin Research

Bacillus Calmette-Guérin (BCG), an inexpensive generic drug, would have the same impact as injecting diabetic mice with Freund's Adjuvant, which stimulates TNF- α production. TNF- α kills the white blood cells responsible for destroying beta cells, and thus prevents, or reverses diabetes. She has reversed diabetes in laboratory mice with this technique, but was only able to receive funding for subsequent research from the Iacocca Foundation, founded by Lee Iacocca in honor of his late wife, who died from diabetes complications. Human trials have begun in 2008.

Diamyd

Diamyd is the name of a vaccine being developed by Diamyd Medical. Injections with GAD65, an autoantigen involved in type 1 diabetes, has in clinical trials delayed the destruction of beta cells for at least 30 months, without serious adverse effects. Patients treated with the substance showed higher levels of regulatory cytokines, thought to protect the beta cells. Phase III trials are under way in the USA and in Europe, with most sites actively pursuing participants. Two prevention studies, where the vaccine is given to persons who have not yet developed diabetes may be the next step.

Diabetes has correctly been labelled as the "silent epidemic"—its nondramatic, insidious and chronic nature often masks the menace inflicted by the disease through death, incapacitation, and negative impact on quality of life of patients as they spend years coping with their life-changing affliction.

Care of Children with Diabetes in the School and Day Care Setting

- Both parents and the health care team should work together.
- School and day care personnel must have an understanding of diabetes and must be trained in its management and in the treatment of diabetes emergencies.

WORLD DIABETES DAY

It is observed annually on November 14 to commemorate the birthday of Frederick Banting who, along with Charles Best, discovered insulin in 1921. Across 130 countries and cosponsored by the International Diabetes Federation

(IDF) and the World Health Organization (WHO), the day was first observed in 1991 in response to concern over the escalating incidence of diabetes around the world.

Diabetes is a silent killer and it is important that everyone in the country is screened for the disease. Government intends to do so in next five years. "Now with the growing cases of diabetes among children, there is a need to have a scheme for children."

Management of Type 1 Diabetes Mellitus in Children and Adolescents Including Recent Advances

Anu Maheshwari, Anju Seth

INTRODUCTION

Type 1 diabetes mellitus (T1DM) is a common chronic disease of childhood. It is caused by deficiency of insulin resulting from the autoimmune destruction of insulin-producing pancreatic beta cells. Challenges in the management of pediatric diabetes are unique and different from those in adult diabetes. These include the obvious differences in the size of the patients, developmental issues such as the unpredictability of a child's dietary intake and activity level, and medical issues such as the increased risk of hypoglycemia and diabetic ketoacidosis. Because of these considerations, the management of a child with type 1 diabetes is more challenging and must take into account the age and developmental maturity of the child.

GOALS OF MANAGEMENT

The therapeutic plan and goals of therapy need to be individualized depending on the parents and the child's abilities, motivation, finances, age, educational status, daily schedule and access to a medical facility. The salient points include:

- Achieving a balance between strict glycemic control, which reduces the risk of long-term sequel and avoidance of severe hypoglycemia, which is more likely with stricter control.
- Setting realistic goals for each child and family. The patient's age and developmental status, and the level of family involvement are important factors that should be accounted for.
- Maintaining normal growth and development.
- Training the patient and family to provide appropriate daily diabetes care in order to attain glucose control within the range of predetermined goals.
- Prompt recognition and treatment of hypoglycemia.
- Increasing independence of the child in diabetes management and self-care as the child grows.

Overview

There are four therapeutic pillars for management of T1DM:

- Insulin therapy
- Meal planning
- Planned physical activity
- Self-monitoring of blood glucose (SMBG) and urinary/blood ketones.

Parental and family involvement is key to successful management. Parents or the child need to be educated regarding insulin therapy, SMBG, diet planning and sick day guidelines. Management of childhood diabetes is team work and needs to include a pediatric endocrinologist or a pediatrician with special interest in diabetes, a dietician, a psychologist, a social worker and a nurse educator.

The initial educational and care phase may occur either in the inpatient or ambulatory setting. Hospitalization for initial management is mandatory if the child is dehydrated, vomiting, breathless, or has features of ketosis. In patients who are not in ketosis at presentation, the indications for hospitalization include age below 5 years of age, parents not confident to administer insulin injections or residence in remote area. There is no single best way to manage diabetes, since the patients vary widely in terms of educational status, economic situation and availability of medical care at hand. On one hand there are intelligent, rich and motivated patients and parents who may opt for the insulin pump or a basal bolus insulin regimen using insulin analogs (3-5 injections a day), perform 5 to 8 blood glucose tests a day and use a meal plan based on carbohydrate counting. On the other end of the spectrum are the underprivileged, uneducated patients with little financial support to buy insulin and syringes, and poor motivation to understand the disease process and life style changes essential for its management. However, majority of patients would fall in between these two extremes; they can easily learn to mix

regular and NPH insulin, inject 2 to 4 times a day and test blood glucose at least 1 to 2 times daily.

INSULIN

Exogenous administration of insulin is needed to replace the deficient hormone and to attain normoglycemia, ideally mimicking the normal physiology. However, this goal remains elusive because of the difficulty in replicating the minute-to-minute variations of physiologic insulin secretion with exogenous insulin administration. There are many different insulin preparations and delivery systems. The selected regimen is individualized for the child and family to fit their lifestyle and optimize compliance while providing glycemic control that meets age-specific goals.

Insulin Preparations

In India, the available insulins include the conventional short acting regular insulin and intermediate acting NPH insulin. Lente and ultra-lente insulins are no longer available. The newer insulin analogs are also available, including rapid-acting analogs lispro, glulisine and aspart; and the long acting basal analogs glargine and detemir. Rapid-acting insulin analogs can be administered after the meal in younger children in whom intake is unpredictable and thus offer a significant advantage in management of younger children and toddlers with diabetes. The approximate time of onset, peak activity, and duration of action of the most commonly used insulins is shown in the Table 1.

Available premixed insulins include mixtures of regular with NPH (in the ratio 50:50 and 30:70) and of soluble rapid acting analogs with a protaminated suspension of the analog (in the ratio 30:70 in the case of aspart insulin and 25:75 or 50:50 in the case of lispro). Use of premixed insulins has the disadvantage that the individual components cannot be adjusted according to individual needs.

Insulin Storage

Insulin vials should be refrigerated at 2 to 8°C and should never be frozen. In households that do not have a refrigerator, insulin should be kept in a cool, dry place away from sunlight. It can be stored in an earthen pot. A vial in use (after the seal has been punctured) should not be used

beyond 3 months if refrigerated or 4 weeks if kept at room temperature.

Insulin Delivery Options and Sites

Insulin is usually injecting using insulin syringe or a pen device. In India, insulin vials are available in two concentrations (40 IU/ml and 100 IU/ml). It is extremely important to ensure that the insulin syringe has the same number of sub-divisions as the strength of insulin preparation in use (i.e. 40 IU syringe for 40 IU insulin vial). For most patients who mix their insulins, syringes are the only option. The pen is more suitable for those on a basal-bolus regimen, different pens being used for delivery of each type of insulin.

Insulin is injected subcutaneously in the upper arm, anterolateral thigh, the anterior abdominal wall (leaving out 2 inches from all sides of the navel) and the upper outer region of the buttocks. The injection area should preferably remain the same for a given time of the day as the rate of insulin absorption is different from each site. Systematic site rotation within the selected area is very important to prevent lipohypertrophy. Insulin requirement is based upon the body weight, age, and pubertal stage of the child. In general, the newly diagnosed child requires an initial total daily insulin dose of 0.5 to 1.0 u/kg. Prepubertal children usually require lower doses. Higher doses are needed in pubertal children, patients in ketoacidosis, or in patients receiving glucocorticoid therapy.

Insulin Regimes

Broadly, there are 2 regimens to give insulin using multiple daily subcutaneous injections: conventional *split-mix regimen* and *intensive basal-bolus regimen*. In recent times continuous subcutaneous insulin infusion is also finding wider use in pediatric practice.

- In the conventional split-mix regimen, which comprises of a mixture of short and intermediate acting insulin, one type of insulin covers one time period: the pre-breakfast short acting covers the period from breakfast to lunch while the intermediate acting works between lunch and dinner; the evening short acting covers the period from dinner to bedtime/midnight while the intermediate acting covers the period from

Table 1: The time action profile of various insulins available in India

Insulin	Onset of action (hr)	Peak action (hr)	Duration of action
Rapid acting analogs	0.25	1	3-4
Human regular	0.5-1	2-4	6-8
Human NPH	1-3	6-8	12-16
Glargine	1	Nil (peakless insulin)	11-24
Detemir	1	3-9	6-23

bedtime to pre-breakfast. The patient usually takes two injections, one pre-breakfast and the other pre-dinner. Generally 2/3rd of the total daily dose of insulin is given before breakfast and 1/3rd before dinner. Each injection is a mixture of rapid or short acting insulin and NPH in the ratio 1:3 for the morning dose and 1:1 or 1:2 for the evening dose. Variation of this regime includes giving evening NPH at bedtime instead of giving it along with evening short acting insulin to prevent pre-breakfast hyperglycemia due to waning of insulin action. In such a situation, stepping up of the pre-dinner intermediate acting insulin to control the pre-breakfast BG may cause nocturnal hypoglycemia.

- The intensive basal-bolus regimens are more physiological and if implemented correctly (with frequent SMBG, corrective supplemental doses of insulin) can give better control. These regimens use rapid or short acting insulin to cover meals and NPH or a basal analog to provide basal insulin (to cover hepatic glucose output in the fasting state). The common regimens in use are:

- *Regular insulin three times a day before each major meal and NPH insulin pre-breakfast plus bedtime*
- *Regular insulin three times a day before each major meal and glargine once a day or detemir twice a day*
- *Lispro, aspart or glulisine insulin before each major meal or large snack (3-5 doses a day) and either NPH/glargine/detemir for basal insulinemia.*

- *Continuous subcutaneous insulin infusion (CSII) or the open loop insulin pump:* It has the advantage that it uses only a rapid acting analog as a continuous infusion for both basal and bolus doses. The bolus can be delivered as a normal bolus, a square wave bolus (for a prolonged meal or a meal with high fat content) or a dual wave bolus (for meals with both rapidly and slowly absorbed carbohydrates and for correcting premeal hyperglycemia). Since there is no insulin depot in the body in pump users, mechanical failure of the pump can lead to rapid onset of DKA. Insulin pumps can give excellent control if all other aspects of diabetes self-management (in particular, meal planning, frequent home based blood glucose monitoring with corrective action) are intensified. A position statement of the ADA, European Society for Pediatric Endocrinology and others recommends that insulin pump therapy should be considered for patients with one or more of the following characteristics: recurrent severe hypoglycemia; wide fluctuations in blood glucose levels (regardless of A1C); suboptimal diabetes control (A1C exceeds target range for age); microvascular complications and/or risk factors for macrovascular complications; good metabolic control, but an insulin regimen that compromises lifestyle. Currently, the extremely high cost of insulin pump is a major limiting factor for wider use of CSII.

The choice of regimen would depend on multiple factors: the age of the child, stage of diabetes, financial condition of the family, school timings, motivation of child and parents, and feasibility of giving multiple shots. The split-mix regimens are the most commonly used in younger children as they are simple for the patient and require fewer daily injections. These regimens lack flexibility of lifestyle which may pose a problem in an infant or an adolescent age group. Basal-bolus regimens should be considered if good control with conventional regimen fails to occur. These can be started at the outset in patients who can afford the additional cost and are also motivated not only to take multiple shots and perform frequent SMBG and act on the results.

A few weeks after the diagnosis and initiation of insulin therapy, a period of decreasing exogenous insulin requirement occurs, commonly referred to as the “honeymoon” or remission phase of diabetes. During this period, the remaining functional beta cells secrete some endogenous insulin resulting in reduced exogenous requirement. Close monitoring of blood glucose is mandatory as hypoglycemic episodes are likely if the insulin dose is not appropriately adjusted. The duration of this phase is variable and may last several months to several years. Rising blood glucose levels, A1C, and increasing exogenous insulin need indicates the end of this phase.

MEAL PLANNING

Nutrition planning is an important component of optimum diabetes management. A dietician with special interest in pediatric diabetes must be part of the diabetes management team. Children and adolescents with T1DM do not need a special diet, unless the child has problems that require particular nutrition needs as in obesity, hypertension, hyperlipidemia, nephropathy and celiac disease. Caloric requirement is same as that for any nondiabetic child. The calorie intake should be adequate so that the child grows normally. What is important, especially in a patient on split-mix regime, is to ensure regular meal timings and consistent carbohydrate intake in each meal to prevent wide swings in blood sugar levels. A fine balance must be achieved between insulin administration, meals and exercise. It is important to prevent hypoglycemia especially in relation to exercise, during night hours and during intercurrent illnesses. Fixed timings (usually a six meal pattern with 3 small and 3 major meals) usually works well for patients on split-mix insulin regimen. The children on basal-bolus regimen can have considerable flexibility in their meal timings and content with the intelligent application of carbohydrate counting and insulin to carbohydrate ratio. This is however not practical in smaller children and infants. Carbohydrates should provide 50 to 60 percent of calories. Sucrose and other simple sugars are no longer forbidden, but their use is better minimized.

Complex carbohydrates and foods with low glycemic index give better postprandial control. A high fiber diet may confer some benefit by slowing absorption of sugar from the gut. Salt intake should be regulated to reduce risk of hypertension. Fats should constitute 30 percent of calories, with restriction of saturated fats to <10 percent and elimination of trans fatty acids. Protein intake should not be higher than the recommendation for healthy children. Protein restriction is needed if micro-albuminuria develops. Sweeteners may be used if necessary in older children but are best avoided. Diabetic snacks are not recommended. These children do not require routine vitamin and mineral supplementation.

Planned Physical Activity

Physical activity should be considered as an important aspect of management of T1DM. Regular physical activity has been demonstrated to improve glycemic control, fitness and muscle strength and psychological wellbeing. Children participating in sports should be supervised and should have access to sweetened drinks and snacks. Blood glucose levels should be monitored before, during and after physical activity. It is important to note that insulin should not be injected into a site that will be heavily involved in muscular activity. A general recommendation is that for every 30 minutes of moderate to intensive sport or physical activity, 15 g or an extra serving of carbohydrate should be consumed. Strenuous physical activity should be avoided if blood glucose concentration is >250 mg/dl, especially if ketones are present.

Sick Day Guidelines

Children whose diabetes is under good metabolic control should not experience more illness or infections than children without diabetes. The diabetes care team should provide clear guidance to patients and families on how to manage diabetes during intercurrent illnesses to avoid the complications of ketoacidosis, dehydration, uncontrolled or symptomatic hyperglycemia and hypoglycemia. Blood glucose and ketones must be checked every 2 to 4 hours. There is only one meter available in India that checks blood ketones and the cost of each ketone strip is very high (Rs 150/-approximately). In practice therefore most patients depend on the less reliable urine ketone tests. A blood glucose level above 180 mg/dl signifies insulin deficiency and the need for additional insulin. Presence of ketones in urine or blood would mean either carbohydrate deficiency due to poor intake (in which case the simultaneous blood glucose would be less than 100 mg/dl) or significant insulin deficiency (when associated with blood glucose over 180 mg/dl). Insulin should never be completely omitted even if child refuses to eat. Insulin dose can be reduced only when blood sugar is below 80 mg/dl and the child cannot eat. In this case, the short or rapid acting insulin dose is omitted

while the intermediate or long acting insulin is continued as usual. When BG is over 180 mg/dl the patient needs a supplement of short or rapid acting insulin immediately. This additional dose is calculated as a percentage of the total daily dose (TDD). The supplement may range from 5 to 20 percent of TDD depending on the BG and the ketone levels. It is always given as regular insulin or rapid acting analog. As a rough guide, when BG is over 180 mg/dl with absent or trace urinary ketones, a supplement of 5 to 10 percent of TDD may be taken; the supplement should be 10 to 20 percent if ketones are small or moderate and 20 percent if ketones are large. The patient who cannot eat his regular meals should be offered plenty of salty liquids (such as rice kanji, vegetable soup, dhal soup, buttermilk, milk without sugar or chicken soup) if BG is above 180 mg/dl and sweet liquids (non-diet soft drinks without fizz, fruit juices, milk with sugar, WHO-ORS or melted icecream) if BG is below 180 mg/dl.

Complications of T1DM

Multiple acute and long term complications may occur in children and adolescents with type 1 diabetes. The most common acute complications include hypoglycemia, hyperglycemia and diabetic ketoacidosis (DKA). The long term microvascular and macrovascular complications include retinopathy, nephropathy, neuropathy and cardiovascular disease. The time interval between onset of diabetes and appearance of complications is directly related to strictness of glycemic control. Poorer is the control; earlier is the onset of complications. Hypoglycemia is discussed here. The management of other complications are beyond the scope of this chapter.

HYPOGLYCEMIA

Hypoglycemia is the result of a mismatch between insulin dose, food consumed, and recent exercise and is rarely, if ever, a spontaneous event. A careful review of blood glucose (BG) records will yield a retrospective prediction of the hypoglycemic event for at least 50 percent of events. Non-modifiable predictors of severe hypoglycemia include age (infancy and adolescence) and longer duration of diabetes. Modifiable predictors are lower hemoglobin A1C (HbA1C) and higher insulin dose for stricter glycemic control.

There is no consistent or agreed upon numerical definition of hypoglycemia for the child with diabetes. Nevertheless, BG values below 60 to 70 mg/dl are generally agreed to place the individual at risk for severe hypoglycemia because values in this range are associated with alterations in the counter-regulatory hormones essential for the spontaneous reversal of hypoglycemia. For clinical use, the value of 65 mg/dl has been most often used as the level for defining hypoglycemia in the pediatric population. In an infant or toddler, BG should be maintained above 100 mg/dl to avoid hypoglycemia. Children on split-mix regimen

often have hypoglycemia if regular snacks or meals are missed especially during the overlap of the peak action of mixed NPH and regular insulin and at night time during prolonged period of fasting. Hypoglycemia can result in abnormal behavior (tantrums in a young child should not be ignored), drowsiness, convulsions, coma, or if prolonged, death. Recurrent hypoglycemia can lead to hypoglycemia unawareness, increasing the risk of later episodes. Parent should be counselled regarding the recognition and management of hypoglycemia. Mild or moderate hypoglycemia, symptomatic or asymptomatic (detected on SMBG), can be managed by patient/parents at home with oral carbohydrates. If the BG is more than 60 mg/dl and the sensorium is normal, the child should be given 5 to 15 g of carbohydrate orally. This should preferably be in the form of free sugars, because the presence of fat delays the absorption of the sugar. Thus the child can be given glucose, sugar, juice or honey. This is followed by a repeat blood sugar testing after 10 to 15 minutes and if still low, glucose should be given again. Severe hypoglycemia, when the patient has altered sensorium (coma or convulsions), requires glucagon or IV glucose and is best managed in hospital settings.

Monitoring of a Child with T1DM: Glycemic Control

Monitoring of glycemic control includes daily monitoring of glucose at home as well as periodic monitoring of overall glycemia over a specified period. The purpose of monitoring glycemic status is to assess level of glycemic control achieved by an individual so that treatment can be fine-tuned, and to help prevent both the acute and the chronic complications of diabetes.

Measurement of immediate glycemic control is best determined by self-monitoring of blood glucose (SMBG) as this provides immediate documentation of hyperglycemia and hypoglycemia, thus helping in finetuning insulin regime. Strict adherence to maintain optimal values of blood sugar by SMBG is seen to be associated with reduction in the levels of HbA1c, thereby reducing the incidence of long term microvascular and macrovascular complications. SMBG is a valuable tool to assess glycemic status during a 'sick day' and can prevent a hyperglycemic or hypoglycemic crisis. SMBG should be done many times every day – before breakfast (fasting), before lunch, before dinner and at bedtime. It should be done at around 2 to 3 AM at least once in a week. There are two types of adjustments in insulin dose based on blood glucose levels. If the premeal sugar is high, then the regular or rapid acting insulin dose to be taken for that meal is to be adjusted upwards. This adjustment is valid for any type of regimen. The second preventive type of adjustment is to be done if high or low reading is observed over a few days. The type of adjustment will differ with the regimen. Adjustments should be made not only in insulin, but also diet, and/or exercise, aimed at preventing the high blood sugar levels. Tables 2 and 3 show preventable insulin adjustments

in split-mix and basal-bolus regimens respectively. The target blood glucose varies based on the age of the child. Young children may suffer more from severe hypoglycemia, and therefore goals of blood glucose levels may be set higher than those for older children and adolescents. Table 4 highlights the 2011 recommendations of the American Diabetes Association on target blood glucose levels in children with diabetes.

Long-term glycemic control is best monitored by blood glycated hemoglobin (hemoglobin A1C). Another method to evaluate long term glycemic control is fructosamine and other glycyated products. Fructosamine measures the glycation of serum proteins such as albumin and reflects glycemia over the preceding 3 to 4 weeks. It is therefore used for the assessment of shorter periods of control than HbA1C. Fructosamine or glycated albumin may be useful in monitoring glucose control over time in individuals with abnormal red cell survival time or in children with thalassemia who concurrently have T1DM. However, fructosamine and other glycated products have not been evaluated in terms of later vascular risk.

Strict glycemic control has been shown to delay the onset of microvascular disease (retinopathy, nephropathy and neuropathy), slow progression of already-present microvascular disease, and decrease the incidence of cardiovascular disease. However, the DCCT (Diabetes control and complication trial) demonstrated that as A1C decreased, indicating a stricter glycemic control, the incidence of severe hypoglycemic episodes increased. Thus, the intensity of glycemic control needs to be balanced

Table 2: Preventive insulin adjustment in mixed split regimen

<i>Blood sugar value</i>	<i>Adjustment</i>	
Pre-breakfast	↑	↑ evening NPH*/ shift to bed- time
	↓	↓ evening NPH
Pre-lunch	↑	↑ morning regular
	↓	↓ morning regular
Pre-dinner	↑	↑ morning NPH
	↓	↓ morning NPH
Bed-time	↑	↑ evening regular
	↓	↓ evening regular

*Before increasing the night NPH check for somogyi phenomenon.

Table 3: Preventive adjustments in basal-bolus regimes using analogs

<i>SMBG reading</i>	<i>Insulin adjustment</i>
Fasting and premeals	Long acting analog
Postmeal	Regular or rapid acting analog

Table 4: Target blood glucose levels

<i>Time</i>	<i>Blood glucose levels age <6 years (mg/dl)</i>	<i>Blood glucose levels age 6-12 years (mg/dl)</i>	<i>Blood glucose levels age > 12 years (mg/dl)</i>
Fasting and premeal	100–180	90–180	90–130
Bedtime and midnight	110–200	100–180	90–150

against the increased risk of recurrent/severe hypoglycemia. Targeted goals for A1C and blood glucose have been defined by a committee of the American Diabetes Association (ADA) based upon the risk of hypoglycemia, with the highest target values set for young children and infants because they have the greatest risk for hypoglycemia. Age-specific goals for A1C are:

- <6 years of age: <8.5 percent
- 6 to 12 years of age: <8 percent
- 13 to 19 years of age: <7.5 percent
- Over 19 years of age: <7.0 percent

Before the emergence of blood glucose monitoring, urine sugar monitoring was used all over the world and diabetic children and their families were able to maintain reasonably good control. Blood glucose monitoring has now replaced urine monitoring in most developed countries, but it may not be feasible for many of our patients to perform 4 to 5 blood sugar tests per day due to the cost involved. Hence, using urine sugar testing in conjunction with blood sugar monitoring is an option when patients cannot do frequent blood glucose monitoring. The downside of this method is inability to detect hypoglycemia.

Urinary ketones should be monitored in a known case of T1DM in case of an infection or illness, stressful situation like surgery, inadequate insulin levels—due to missed dose and hypoglycemia. Parents should be informed regarding the monitoring of urinary ketones by means of a urinary ketostix in setting of fever with tiredness and loss of appetite, nausea and vomiting, rapid respiration, abdominal pain and drowsiness or loss of consciousness. If blood sugar is consistently >250 mg/dl, ketone body measurement is a must even if the child is asymptomatic.

Monitoring of a Child with T1DM: Long Term Complications

A child with diabetes should be under a regular follow-up. A complete physical examination should be performed at least twice a year and includes the following:

- Height and weight: Monitor for normal growth and weight gain. Poor growth may indicate poor glycemic control or presence of co-morbidities like hypothyroidism, celiac disease or an infection.
- Blood pressure: Screen for hypertension
- Pubertal assessment: Because puberty increases insulin resistance, increased insulin requirement can be anticipated by identifying early signs of puberty. Poor

glycemic control is often associated with delay in onset of puberty.

- Thyroid: Check for thyroid enlargement to screen for autoimmune hypothyroidism, a condition frequently associated with type 1 diabetes.
- Skin: Examination of injection sites for evidences of lipo-hypertrophy or atrophy that can alter insulin absorption rates.
- Eyes: All patients should have regularly scheduled dilated fundoscopic examinations. Examination without dilation of the pupils is of little value as a screen for retinopathy because diabetic retinopathy usually starts at the periphery of the retina. Annual ophthalmologic examination is needed for children ≥ 10 years of age and 3- to 5-year duration of diabetes to screen for retinopathy.
- Extremities: As the disease duration increases, extremity examination for evidence of limited joint mobility (sclerodactyly, joint or finger stiffness) or peripheral neuropathy (feet) especially the vibratory sense as it is a marker of early neuropathy. Annual foot examination should be done to evaluate foot health and screen for neuropathy in children ≥ 10 years of age.

Laboratory Parameters

- A1C, every three months
- Annual screening for microalbuminuria for children ≥ 10 years of age and five-year duration of diabetes — Screen for nephropathy
- Celiac disease screening (anti-TTG [tissue transglutaminase]) at diagnosis and every other year
- Lipid profile: Screen for dyslipidemia once puberty begins, and if normal, repeat the screen every five years. If abnormal, screen yearly as recommended in the ADA guidelines. However, children who are in poor glycemic control may manifest new lipid abnormalities. Therefore, it is important to rescreen at the time of a prolonged episode of poor glycemic control.
- Thyroid function testing: Screening for autoimmune hypothyroidism every one or two years or if features of hypothyroidism or if an enlarged thyroid are evident.

RECENT ADVANCES

Alternative Routes of Insulin Delivery

There is resistance to the use of insulin by patients because of its need to be injected subcutaneously and concerns

regarding potential effects on lifestyle, risk of hypoglycemia, and perception that people treated with insulin are “sicker”. Alternative, less invasive options for insulin therapy are therefore desirable. Oral administration has not been found to be effective as it results in loss of bio-potency due to breakdown in the stomach. Other routes of administration have been explored, including transdermal, buccal, nasal, and inhaled delivery. An inhaled form of rapid-acting insulin was available for a short time, offering the first new insulin delivery option (Exubera) since insulin’s discovery in the 1920s. However, it involved use of a bulky device to dispense insulin as a dry-powdered formulation with little dosing flexibility and a variable insulin delivery. Thus, it has been withdrawn since 2007. A different inhaled insulin formulation, which appears to have a more convenient delivery system and greater dosing flexibility, is in development. This formulation (Technosphere) contains recombinant human insulin dissolved with powder (fumaryl diketopiperazine). Once inhaled, the insulin is rapidly absorbed upon contact with the lung surface. Both the insulin and the powder are nearly completely cleared from the lungs of healthy individuals within 12 hours of inhalation; only 0.3 percent of the insulin and 0.4 percent of the powder concentration remain after 12 hours. In contrast, with the exubera formulation, about 8 to 9 percent of the inhaled dose remained in the lungs 12 hours later.

Continuous Glucose Monitoring

Subcutaneous glucose sensors that continuously measure interstitial fluid glucose levels are now available and approved for use in children. The currently available continuous monitoring systems are expensive and relatively inaccurate in the lower (<70 mg/dl) glucose range thus limiting their usefulness. The first generation of continuous glucose monitors provided blood glucose data only after downloading by the physician, and did not provide real-time feedback to the patient. This type of device did not appear to improve glycemic control in children, although there was some educational value in detecting patterns of blood glucose fluctuations and episodes of hypoglycemia during periods of sleep. The newer generation of continuous monitors report blood glucose levels to the patient in real time. Short-term studies indicate clinical benefits of these devices as compared to conventional methods of blood glucose monitoring, when used by motivated and well-informed patients. Studies are currently evaluating the efficacy of a fully automated closed loop system of insulin delivery based on continuous glucose sensing.

Immunomodulators

The increase in understanding of the pathogenesis of type 1 diabetes mellitus has made it possible to consider interventions to slow the autoimmune disease process in an attempt to delay or even prevent the onset of hyperglycemia. Multiple immunomodulators have been tried with variable

response. Azathioprine, mycophenolate mofetil alone or in combination with daclizumab failed to show significant remission beyond 1 to 2 years. Cyclosporine was studied in large-scale trials of recent diabetics in Canada and France. It was found that remissions were twice as common in the cyclosporine-treated patients, as compared with placebo. However, almost all patients required insulin again within three years. An analysis of subjects recruited into the Canadian-European cyclosporine trial showed that subjects who were IA-2 negative at entry to the trial were more likely to respond to cyclosporine (with a decrease in insulin requirements and an increase in C-peptide secretion) than IA-2 positive subjects. Immunotherapy with DAB486-IL-2, GAD65, Bacillus Calmette-Guerin (BCG), DiaPep277 have been tried with variable results. Anti-inflammatory drugs like TNF-alpha inhibitors, Etanercept and interferon alpha have all been tried with no results. Nicotinamide supplement was ineffective in the nicotinamide diabetes intervention trial (ENDIT) trial. A primary prevention trial of the effect of docosahexaenoic acid (an omega-3 fatty acid) on the natural history of type 1 diabetes is in progress. Another approach is based upon the possible immunogenicity of the complex dietary proteins found in cow’s milk and thereby avoiding cow’s milk.

SUMMARY

Optimal management of a child with diabetes is defined by the implementation of a care plan that maintains glucose control as near to normal as safely possible, balancing the risks of long-term sequelae and hypoglycemia. This requires comprehensive case management and intensive training of the parents. Diabetes education and self-management training by a pediatric diabetes multidisciplinary team provides the ideal setting to acquire the knowledge and skills needed for care. In the initial phase, the team teaches the family about the disease process and skills required for daily care (administering insulin, blood glucose monitoring, testing for urine ketones, and recognizing and treating hypoglycemia). The ability of the child to participate in self-management varies with the age, cognitive abilities, and emotional maturity of the child or adolescent. Intensive compared to conventional therapy improves glycemic control and decreases long-term complications of diabetes. Frequency of follow-up visits is tailored to the needs of the child and family. Follow-up visits monitor the child’s glycemic control and growth with appropriate readjustments to the management plan. On-going visits allow for continued family education and screening for complications of diabetes.

Approach to Goiter in Children

Mohit Kehar

INTRODUCTION

A goiter is an enlargement of the thyroid gland. Persons with enlarged thyroids may have normal function of the gland (euthyroidism), thyroid deficiency (hypothyroidism), or overproduction of the hormones (hyperthyroidism).

Clinically goiter is defined as enlargement of the lobes greater than the terminal phalanx of the patient's thumb.

WHO CLASSIFICATION/GRADING

- 0: No goiter
- 1a: Palpable lobe
- 1b: Noticeable gland on neck hyperextension
- 2: Gland noticeable with neck in normal position
- 3: Visible gland at a distance of 10 m.

There have been various reports which showed the discrepancy of palpation and USG assessment in evaluation of goiter, palpation is relatively inaccurate for assessing the prevalence of goiter in mild iodine deficiency, thyroid volume measurement by ultrasound in children provides a useful tool for the assessment of goiter in mild iodine deficiency.

Formula for thyroid volume (formula of a rotation ellipsoid model): width \times length \times thickness \times 0.52 for each lobe. Table 1 gives the size of thyroid at various ages.

DIFFERENTIAL DIAGNOSIS OF GOITER

The enlargement of the thyroid is generally mediated by an increase in the pituitary-derived thyroid stimulating hormone (TSH) or in antibodies that bind to the TSH receptor, such as the thyroid stimulating immunoglobulin's (TSIs) found in Graves' disease. Inflammation or infiltration may cause diffuse, symmetrical enlargement, although the gland is usually asymmetric and nodular. The most common inflammatory process is autoimmune

thyroiditis.¹ More often following careful investigation no underlying cause can be identified for diffuse euthyroid enlargement often termed as simple colloid goiter. Table 2 gives the causes of thyroid enlargement.

Table 1: Thyroid volume according to age

Age (years)	Volume (ml) mean \pm SD
7	3.1 \pm 1.3
8	3.3 \pm 1.2
9	3.6 \pm 1.3
10	4.0 \pm 1.5
11	4.9 \pm 1.5
12	5.3 \pm 1.4
13	6.1 \pm 1.6
14	6.3 \pm 1.5

Table 2: Differential diagnosis

- Autoimmune thyroid disease
 - Chronic lymphocytic thyroiditis (Hashimoto's thyroiditis)
 - Graves' disease
- Colloid (simple) goiter
- Goitrogen exposure and drugs like lithium, etc.
- Dyshormonogenesis
- Infectious
 - Subacute (viral) thyroiditis
 - Chronic suppurative thyroiditis
- Anatomic abnormalities
 - Thyroglossal duct cyst
 - Hemigenesis of the thyroid
- Nodular goiter
 - Solitary nodule (adenoma, carcinoma, cyst)
 - Multinodular goiter secondary to autoimmune thyroid disease

CLINICAL AND INVESTIGATIVE EVALUATION OF PATIENT WITH GOITER

While evaluating a patient of goiter we should ask for family history of thyroid disease, consanguinity, geographical area of residence, exposure to irradiance, medication history, goitrogens, and in newborns history of maternal exposure to iodine or antithyroid drugs, symptoms suggestive of hyperthyroid or hypothyroid.

While examining a patient, general physical examination should be done, including vitals. We should look for features/signs suggestive of hypo/hyperthyroidism. The neck is then examined and thyroid is examined for nodularity, consistency, surface, and texture, signs of compression, lymphadenopathy, and bruits. A symmetric, diffuse enlarged gland needs an evaluation for hyperthyroidism and primary hypothyroidism. One should look for the scars, asymmetry and any neck swelling. Erythema overlying a tender swelling may be due to suppurative thyroiditis or infected thyroglossal cyst or brachial cleft cyst. Goiter due to dysmorphogenesis varies in size and tends to be softer in consistency with or without bruits. Disturbance in thyroid function and multinodularity usually excludes malignancy as opposed to a firm, irregular, painless single nodule.

In determining the cause of thyromegaly (Flow chart 1) the initial diagnostic evaluation should be limited to measurements of TSH and thyroid antibodies. The T4 level is required only if the TSH level is elevated. Free T4 measurement is preferred to the total T4 level because the former is not influenced by thyroid binding globulin levels and, therefore, better reflects the active thyroid hormone level. Thyroid antibody titers greater than 1:2000 or 10 mIU/L most likely indicate autoimmune thyroiditis.^{2,3}

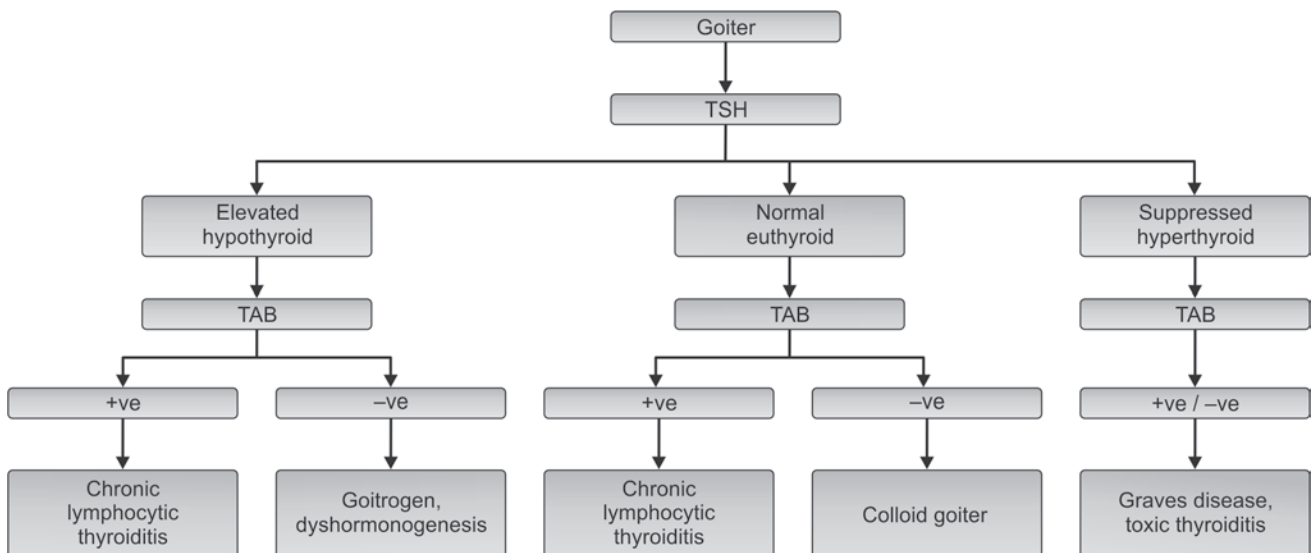

Lower levels may simply reflect a nonspecific inflammation of the thyroid gland. Imaging is only required if a solitary nodule is suspected.

GOITER AND HYPOTHYROIDISM

The most common cause of acquired hypothyroidism is chronic lymphocytic thyroiditis. Chronic lymphocytic thyroiditis (CLT), also known as Hashimoto's thyroiditis is uncommon in children younger than four years of age. The peak age of onset in the first-two decades of life is in early to midpuberty. The ratio is 2:1 in favor of females versus males; this ratio is less skewed than in adulthood when 90 percent of cases occur in females. Although there is no defined pattern of inheritance, a family history is reported in 30 percent of affected children. It is well established that the risk of CLT is higher in individuals with chromosomal abnormalities such as Turner syndrome, Klinefelter syndrome and Down syndrome. There is also an increase in association with other autoimmune diseases. The prevalence of thyroid autoantibodies in children and adolescents with type 1 diabetes has been reported to be as high as 20 to 40 percent, while abnormal thyroid function is reported in approximately 7 percent of these patients.

Autoimmune thyroid disease may be associated with a euthyroid state, hypothyroidism or hyperthyroidism. In the early stages, when examined the gland will be smooth and soft, progressing to a granular or pebbly texture, and then becoming firm and irregular. It has been seen that most children are euthyroid at diagnosis. Hypothyroidism will be present in 3 to 13 percent of patients, and they will show typical symptoms, 3 to 35 percent of patients have elevated TSH concentrations and normal T4 levels, a state termed subclinical or compensated hypothyroidism.

Flow chart 1: Most common causes of a goiter – negative (-ve); positive (+ve); thyroid antibodies (TAB); thyroid stimulating hormone (TSH)

Rarely, children may present with transient thyrotoxicosis with suppressed TSH, and elevated serum T3 and T4 levels, a condition known as toxic thyroiditis or hashitoxicosis.

An endemic goiter is the most common preventable cause of mental retardation. However, because of the routine addition of iodine to salt in the western world, it is not seen in that area. Goitrogen exposure should be considered in patients with a goitre and negative thyroid antibodies, and it will generally be evident from the patient's history. In addition to prescribed medications, it is important to ask about the use of over-the-counter preparations, such as iodide-containing expectorants and natural remedies. Dyshormonogenesis usually presents as congenital hypothyroidism, however, milder forms may present later as acquired hypothyroidism with goitre and negative thyroid antibodies. A family history should be sought because this is an autosomal recessive condition. While hypothyroidism may also occur if a patient has hypothalamic and pituitary lesions (i.e. tertiary and secondary hypothyroidism, respectively), a goitre is not a clinical feature of these cases.

Symptoms of Hypothyroidism

Deceleration of growth, goiter, which may be a presenting feature, typically is non tender and firm, with a rubbery consistency and a pebbly surface. Myxedematous changes of the skin, there will be constipation, cold intolerance, an increased need for sleep develop insidiously. Osseous maturation is delayed, adolescents typically have delayed puberty, whereas younger children may present with galactorrhea or pseudoprecocious puberty.

Treatment

The decision to treat with l-thyroxine is clear for overt hypothyroidism, but controversial for a euthyroid goiter or compensated hypothyroidism. In overt hypothyroid patients levothyroxine given orally is the treatment of choice, newborn require 10 µg/kg/24 hours and children with hypothyroidism require about 4 µg/kg/24 hours, and adults require only 2 µg/kg/24 hours.

For patients who are compensated the approach used is to monitor patients with mild elevations of TSH level (less than 10 mIU/L) six months after the diagnosis is confirmed and then annually. Repeat levels of TSH are often normal. In those patients with a confirmed TSH level that is greater than 10 mIU/L, treatment with thyroxine is usually continued until growth is complete. Thyroid status is then reassessed to determine the need for ongoing treatment. Patients with a TSH that is greater than 20 mIU/L have a high rate of progression to hypothyroidism, and are treated with thyroxine.⁴

SIMPLE GOITER (COLLOID GOITER)

The most common causes of euthyroid goiter in childhood are CLT and a colloid goiter. Thyroid enlargement that is not caused by inflammatory, infectious or neoplastic causes is termed a colloid goiter, also. Histological findings seen in cases of colloid goiter include enlarged thyroid follicles filled with abundant colloid. The cause remains controversial. Although TSH is the principal growth-stimulating factor for the thyroid, TSH levels are normal in patients with colloid goiter. The condition predominates in girls and has a peak incidence before and during the pubertal years. The goiter may be small or large. It is firm in half the patients and occasionally is asymmetric or nodular. Levels of TSH are normal or low, scintiscans are normal, and thyroid antibodies are absent. The natural history is for spontaneous reduction with time, and treatment with thyroxine is not indicated.

GOITER AND HYPERTHYROIDISM

Hyperthyroidism results from excessive secretion of thyroid hormone and during childhood is mainly due to Graves' disease. Other causes are rare and should be suspected only when there is an atypical presentation.⁵ As seen with other thyroid disorders females are predominantly affected and the ratio of affected females versus males is less pronounced than in adulthood. A family history of autoimmune thyroid disease is commonly present.

Other rare causes of hyperthyroidism that have been observed in children include toxic uninodular goiter (Plummer disease), hyperfunctioning thyroid carcinoma, thyrotoxicosis factitia, subacute thyroiditis, and acute suppurative thyroiditis. In infants who are born to mothers with Graves' disease, hyperthyroidism is almost always a transitory phenomenon; classic Graves' disease during the neonatal period is usually rare.

Graves' disease is an autoimmune disorder in which there is production of thyroid-stimulating immunoglobulin (TSI) which results in diffuse toxic goiter. About 5 percent of all patients with hyperthyroidism are younger than 15 years of age and the peak incidence in these children occurs during adolescence.

Manifestations of Hyperthyroidism

Symptoms include nervousness, irritability, heat intolerance, excessive sweating, palpitations, fatigue and weakness, weight loss with increased appetite, frequent bowel movements, and oligomenorrhea. Patients are anxious, restless, and fidgety. Skin is warm and moist, and fingernails may separate from the nailbed (Plummer's nails). Eyelid retraction and lid lag may be present. Cardiovascular findings include tachycardia, systolic hypertension, systolic murmur, and atrial fibrillation. A fine tremor,

hyperreflexia, and proximal muscle weakness may also be present. Long-standing thyrotoxicosis may lead to osteopenia. In Graves' disease, the thyroid is usually diffusely enlarged to two to three times its normal size, and a bruit or thrill may be present. Infiltrative ophthalmopathy (with variable degrees of proptosis, periorbital swelling, and ophthalmoplegia) and dermopathy (pretibial myxedema) may also be found. In subacute thyroiditis, the thyroid is exquisitely tender and enlarged with referred pain to the jaw or ear, and sometimes accompanied by fever and preceded by an upper respiratory tract infection.

Evaluation

The diagnosis of Graves' disease is made by finding a suppressed TSH level with elevated T4 and/or T3 levels. When the patient's clinical presentation is mild, free T4 levels may be high normal, with an inappropriately suppressed TSH, in which case T3 levels should be measured. Antithyroglobulin antibodies and thyroid peroxidase antibody levels may be positive but they are not pathogenic. TSI, if measured, will be positive.

Hashitoxicosis can present similar to Graves disease. However, hashitoxicosis is a self-limiting condition and lacks ophthalmopathy. It is caused by autoimmune damage to follicular cells, resulting in the release of preformed T4 and T3 into circulation. Transient or permanent hypothyroidism may follow a period of hyperthyroidism. If the hyperthyroidism lasts more than a few weeks, the diagnosis of hashitoxicosis is usually unlikely.

Subacute thyroiditis is generally caused by viral infections and is generally not seen in pediatric age group. Children with subacute thyroiditis have an enlarged, tender thyroid, malaise, fatigue and weakness that develop after an upper respiratory tract infection. There are two distinct phases in the progression. During the acute stage (two to six weeks), preformed T4 and T3 are released from the inflamed thyroid follicles, resulting in hyperthyroidism with or without clinical symptoms. For the next two to seven months, the damaged thyroid is less effective at synthesizing hormone, resulting in low to normal T3 and T4 concentrations with a compensatory elevation of TSH. Nearly all patients recover from hypothyroidism.

Autonomously hyperfunctioning adenomas secrete T3 and cause mild hyperthyroidism. The thyroid is usually of small or normal size with a palpable nodule. Symptoms of hyperthyroidism generally occur when the nodule is greater than 2.5 cm in diameter. The nodules are rarely malignant, and surgery is curative in such cases.

Treatment

Most centers recommend initial medical therapy using antithyroid drugs rather than radioiodine or subtotal

thyroidectomy, although radioiodine is gaining acceptance as initial treatment in children >10 years of age. The 2 antithyroid drugs in widest use are propylthiouracil (PTU) and methimazole, the initial dosage of PTU is 5 to 10 mg/kg/24 hours given 3 times daily, and that of methimazole is 0.25 to 1.0 mg/kg/24 hours given once or twice daily. A β -adrenergic blocking agent like propranolol (0.5–2.0 mg/kg/24 hours po, given 3 times daily) supplemented to antithyroid drugs in the management of severely toxic patients. Surgery or radioiodine treatment is indicated when adequate cooperation for medical management is not possible, when adequate trial of medical management has failed to result in permanent remission, or when severe side effects preclude further use of antithyroid drugs. The eye changes remit gradually; severe ophthalmopathy may require treatment with high-dose prednisone, orbital radiotherapy, or orbital decompression surgery.

NODULAR GOITER

Thyroid nodules are relatively common in adolescents these nodules are usually asymptomatic and often discovered incidentally, but they raise the fear of cancer. A multinodular goiter is almost invariably caused by Hashimoto's thyroiditis and it carries a good prognosis. The asymptomatic, solitary thyroid nodule is a thyroid adenoma, thyroid carcinoma or a thyroid cyst. Thyroid carcinoma occurs in approximately one per one million persons/year in the first-two decades of life.⁶

A large-sized nodule (more than 4 cm) which is rapidly growing has a hard texture with fixation to adjacent structures, associated with regional lymphadenopathy and hoarseness or dysphagia are suspicious clinical features, increasing the probability of malignancy.

Investigation of a solitary nodule should begin with thyroid function tests and thyroid antibodies. Thyroid cancer is unlikely in the presence of hypothyroidism, hyperthyroidism or autoimmune thyroiditis.⁷ The first line investigation is thyroid ultrasound. It will identify other cervical masses that can be confused with a thyroid nodule, such as a thyroglossal duct cyst, and determine whether the nodule is cystic, solid or mixed. If a purely cystic thyroid nodule is identified, no further investigations are required and the patient may be followed conservatively. If, however, the lesion is solid or of mixed density, then radionuclide scanning (^{99m}Tc-pertechnetate, ¹²³I or ¹³¹I) is indicated to differentiate a hyperfunctioning (hot) from a hypofunctioning (cold) nodule. A hyperfunctioning nodule is, most likely, a benign hyperfunctioning adenoma. A cold nodule in a pediatric patient has a more likelihood of malignancy than in adults with cold nodule.

Menstrual Problems in Adolescents

Harsha Khullar

Menarche is the first menstrual period in life. Average age in western world is 12.8 years for white and 12.6 years for black adolescents (Mac Mohan B). It may occur anywhere between 10 and 16 years. The peak age is 13 years in India with mean age of 14 years.

Menstruation is the cyclic physiologic shedding of the endometrium due to action of hormones in the presence of intact hypothalamus-pituitary-ovarian axis.

Three very important components for it to occur are:-

- Endometrium must respond to the hormones, i.e. estrogen and progesterone.
- Outflow tract, i.e. passage should be patent.
- Normal genetic karyotype, i.e. 46 XX.

Any problem with the above stated can lead to menstrual problems.

Normal menstrual cycle is the cyclic bleeding with an average rhythm of 28 ± 7 days with 4 to 6 days of bleeding.

Normal interval for menstruation is 21 to 45 days with little cycle to cycle variation in adults (Beach et al). Adolescents show more variations in cycle length than do adults and have a normal duration of flow of 3 to 7 days.

Abnormal bleeding in adolescents is a common problem and a difficult situation for a gynecologist to deal with. Almost 50% of adolescent girls visit to gynecologist with abnormal bleeding.

Various menstrual disturbances terminology is as follows:

- Amenorrhea
- Oligomenorrhea
- Polymenorrhea
- Menorrhagia
- Menometrorrhagia
- Hypomenorrhea
- Intermenstrual bleeding

Amenorrhea is the absence of menstruation. It may be:

- Physiological or
- Pathological

PHYSIOLOGICAL AMENORRHEA

Prevails prior to puberty, during pregnancy and lactation and post menopause.

Pathological amenorrhea may be due to:

- Systemic disease
- Endocrinopathies
- Hypothalamo-pituitary-ovarian-uterine axis disturbance
- Psychological factors
- Drug usage
- Genetic factors

Amenorrhea may be:

- Primary
- Secondary

Primary amenorrhea is the failure of onset of menses beyond 16 years of age in the presence of secondary sexual characteristics development.

Various causes of primary amenorrhea can be grouped into 5 levels: (Speroff)

Level I—Extrinsic to hypothalamo-ovarian axis. These include:

- Systemic diseases
- Thyroid and adrenal disorders
- Physiological
- Pregnancy and lactation

Level II—Hypothalamic

- Congenital: Kallman's syndrome
- Acquired:
 - Pituitary stalk disconnection syndrome
 - Excessive weight loss
 - Excessive weight gain
 - Craniopharyngioma
 - Cranial radiotherapy

Level III—Pituitary:

- Tumors

- Prolactinomas
- Non-functional tumors
- Infection: Tuberculosis
- Radiotherapy, surgery

Level IV–Ovarian

- Polycystic ovarian syndrome
- Premature menopause (ovarian failure)
- Ovarian agenesis, dysgenesis (Turner syndrome)
- Chemotherapy/Radiotherapy/Surgery

Level V–Uterovaginal

- Uterus agenesis
- Testicular feminisation
- Imperforate hymen
- Radiotherapy

Secondary Amenorrhea: is the absence of a period for more than 6 months.

To evaluate a case of amenorrhea:

- Establish presence of secondary sex characters
- Exclude anatomical causes and chromosomal cause
- Look for signs of virilization and hirsutism
- Calculate BMI
- Local examination to see for imperforate hymen.
- Ultrasound to establish the presence or absence of uterus

In the absence of secondary sex characters development the clinician should start investigating the patient after the mean age of menarche, i.e. 14 years but the investigations may be delayed to 16 years in their presence in case of primary amenorrhea.

Baseline investigations include:

- FSH, LH,
 - Thyroid function test and
 - Serum prolactin,
 - Antimüllerian hormone for ovarian reserve.
- Progesterone challenge test to evaluate the level of endogenous estrogen and the integrity of outflow tract.
- Positive bleed: confirms a functional outflow tract
- No bleed suggests either outflow obstruction or absent estrogen effect on the endometrium.
- Serum prolactin: If high, MRI brain should be done to rule out pituitary tumor.
 - Gonadotropic hormones, if normal or low- hypothalamus amenorrhea.
 - High levels of gonadotropin indicate primary ovarian failure.

MANAGEMENT OF PRIMARY AMENORRHEA**Imperforate Hymen**

Patient may present with cyclical abdominal pain, sometimes urinary retention due to vaginal distension (hematocolpos).

Examination reveals a palpable suprapubic mass. Vulval examination reveals a blue colored membrane at vaginal opening.

It can be managed by a cruciate incision of the membrane under general anesthesia.

It should be a slow decompression.

Absence of Uterus and Vagina

Complete androgen-insensitivity syndrome is an X linked disorder where it is a phenotypically female with well developed breasts and external genitalia with genetically male XY karyotype. In such cases testes are found in the inguinal canal or abdomen. The testes should be removed because of the risks of malignancy.

Tuberculosis has to be ruled out. The incidence of tuberculosis with primary amenorrhoea is 3 to 4 percent.

Oligomenorrhea/Hypomenorrhea

In this the pattern of menstrual cycle extends to cycle length exceeding 35 days. It is compatible with normal reproductive capacity. The causes are similar to that of amenorrhea, genital tuberculosis and polycystic ovarian disease.

Hypomenorrhea means scanty menses with regular cycles. The main causes include causes of oligomenorrhea, genital tuberculosis, Asherman's syndrome (uterine synechiae)

Polymenorrhea/Epimenorrhea

In this the cycles are short (21 days or less) with heavy bleeding. The cause of the ovarian overactivity seems to be the result of disturbed endocrine axis.

Menorrhagia

It is the excessive bleeding with regular cycles.

Metrorrhagia

Irregularly timed episodes of bleeding superimposed on normal cyclical bleeding.

Menometrorrhagia

Excessive prolonged bleeding that occurs at irregularly timed and frequent intervals.

Intermenstrual Bleeding

It is the bleeding occurring in between otherwise normal menstrual cycles.

Menstrual disturbances in adolescents whether actual or perceived are mainly:

- Dysmenorrhea
- Irregular menses
- Excessive menstrual bleeding

Dysmenorrhea

The most frequent complaint in adolescent girls is dysmenorrhea. It is classified as:

- Primary or
- Secondary.

Primary Dysmenorrhea

It starts on the first day of the period and lasts for 12 to 24 hours. It only occurs in ovulatory cycles. The first menses are usually anovulatory. It usually does not present until ovulation has been established.

Secondary Dysmenorrhea

It usually starts before menses and lasts till the bleeding lasts. It is predictive of uterine or pelvic pathology like uterine fibroids, endometriosis, or pelvic adhesions.

Adolescents Usually have Primary Dysmenorrhea

Cause of dysmenorrhea in adolescents:

- Five to ten percent of adolescents miss school due to this
- It is thought to be caused by increased prostaglandin synthesis
- Usually there is family history, i.e. her mother or sister might have suffered from it. More than 20 percent of patients with dysmenorrhea report that their mothers or sisters also had similar problems.

MANAGEMENT

- Complete history
- Differentiate primary from secondary dysmenorrhea
- Prostaglandin synthetase inhibitors are used as pain killers.
- Symptomatic relief is reported by 70 percent of patients with PG synthetase inhibitors (mefenemic acid, naproxen sodium when started premenstrually).
- In girls who need contraception or those not responding to analgesics combined oral contraceptive pills provide effective pain relief.
- Study by Robinson shows that adolescents who improve symptomatically with OCs are eight times more likely to continue treatment.
- If there is no improvement further investigations in the form of ultrasound, laparoscopy/hysteroscopy are performed to rule out any pathology.

Irregular Menstrual Cycles

- Forty-five percent of adolescents do not ovulate for 1 to 2 years after menarche. Hence, it is not surprising that irregular or infrequent cycles are a common occurrence in this age group.
- Lack of regular menstruation is a common cause of concern especially for the mothers of girls at this age.
- It is very important to reassure the patient and her mother, that this is a self-limiting problem.
- If previous cycles were regular with infrequent cycles now, further assessment is necessary.

In patients with regular periods, with polymenorrhea, the most common reason is suppression of hypothalamic or pituitary function caused by emotional stress. Acute

weight loss and excessive exercise can also lead to polymenorrhea, oligomenorrhea or amenorrhea. Anorexia nervosa is another cause for the same.

- Polycystic ovaries can cause oligomenorrhea. It can be diagnosed by LH/FSH ratio, androgen levels and classic ovarian ultrasound picture.
- Androgen producing ovarian tumor can cause amenorrhea with virilizing changes.
- Rarely adrenal tumors can cause amenorrhea.

Clinical assessment and investigation approach to these patients depend on the most likely underlying problem.

Cycle regularity can be restored with combined estrogen-progesterone preparations.

Polymenorrhea in adolescents is usually caused by luteal phase dysfunction. These patients respond well to either progestogen treatment in the luteal phase or combined estrogen progestogen preparation.

Assessment of any coagulation disorder or blood dyscrasias should also be included in the management of patients with polymenorrhea.

Puberty Menorrhagia

Puberty menorrhagia is defined as bleeding occurring between menarche and 19 years.

There is immaturity of the hypothalamus and inadequate positive feedback resulting in excess levels of estrogen. Approximately 20 percent of adolescents have an underlying endocrine or some other disorder which needs further investigations.

During puberty, maturation of the hypothalamus-pituitary-ovarian-axis is characterized by an increase in the frequency and amplitude of pulsatile GnRH, which initiates and regulates secretions of pituitary gonadotropins.

During pre pubertal years, LH is secreted primarily at night in an episodic fashion. With progression to puberty, LH peaks increase in pattern similar to that seen at night. The timing of these LH pulses is crucial in establishing normal ovulatory cycles. Increase in basal LH as well as immature timing of pulses result in anovulatory cycles. These cycles are characterized by levels of LH and FSH secretion that are sufficient to induce follicular development and estrogen production but inadequate to induce follicular maturation and ovulation. Thus unopposed estrogen stimulates endometrial growth. This ultimately outgrows the blood supply and architectural support, resulting in partial breakdown and shedding in an irregular manner.

Equal amounts of PGF2 α (vasoconstrictor and weak platelet aggregator) and PGE2 (vasodilator with weak platelet antiaggregatory effect) are synthesized in the endometrium in proliferative phase whereas levels of PGF2 α progressively increase during luteal phase under the influence of estradiol and progesterone. During normal menstruation, ratio of PGF2 α : PGE2 is 2:1, i.e. the vasoconstrictor effect is more than vasodilator effect.

During anovulatory cycle there is lack of progesterone resulting in decreased PGF 2α and PGE 2 ratio, i.e. vasodilator effect is more than vasoconstrictor effect. This results in increased blood loss and painless periods.

In a study by Sanjay Rao et al 80 percent of cases of puberty menorrhagia, the cause was anovulatory.

Simultaneously the patient with puberty menorrhagia should be evaluated for hematological status to rule out blood dyscrasias. Classens and coworkers have reported that 19 percent of adolescents with menorrhagia requiring hospital admission suffered from coagulation disorder. Various hematological disorders leading to heavy periods are:

- Idiopathic thrombocytopenia purpura
- Von Willebrand's disease
- Leukemia
- Platelet dysfunction like Glanzmann's thrombasthenia.

Investigations

- Rule out pregnancy by urine pregnancy test
- Complete blood count with peripheral smear
- Coagulation profile
- Blood group and Rh
- Thyroid function tests
- Hormonal assays (LH, FSH, Prolactin)
- Ultrasound whole abdomen and pelvis
- X-ray chest

Management of Puberty Menorrhagia

- Good history
- Physical examination
- Rule out pregnancy, thyroid disease, hypoprolactinemia and coagulation defects
- Young girls should be advised to maintain menstrual diary referring to frequency and heaviness of her periods.
- If the periods do fall within normal limits, reassure the patient.
- If periods are heavy with regular cycles PG synthetase inhibitors such as mefenamic acid or tranexamic acid can be advised during the days of heavy flow.
- If periods are irregular, hormone treatment is advised. Norethisterone or dydrogesterone 5 mg thrice daily from 15th to 25th day of period may be advised.
- In case of heavy bleeding intravenous conjugated equine estrogen is effective. It stimulates fibrinogen production factors V and IX and platelet aggregation is also stimulated.

Estrogen therapy yields very good results and brings heavy bleeding under prompt control but it is not recommended due to its high dosage and associated side effects.

- The choice of treatment is progestogens and oral contraceptives. OC pills are of use due to its ease of use and ability to regulate the cycle.
- Oral medroxyprogesterone acetate 60 to 120 mg oral followed by 20 mg/day for 10 days
- Mirena (progesterone intrauterine device) controls bleeding in resistant cases by thinning endometrium. It cannot be used in virgin girls.
- Desmopressin (synthetic analog of arginine vasopressin, IV or nasal spray 1.5 mg/ml is administered in von Willebrand's disease)
- In rare cases of arteriovenous aneurysms uterine artery embolization has been reported.
- The use of GnRh analog is controversial. These may be used in patients with hematological disorders and when coagulopathy is predictable as in patients undergoing chemotherapy and bone marrow transplantation.
- Danazol is contraindicated in young girls as it may cause hirsutism.
- If young girl fails to respond to medical therapy endometrial curettage is done to rule out genital tuberculosis.
- Simultaneously oral iron should be prescribed to control anemia.

CONCLUSION

- The management of menstrual disorders in adolescents begins with the explanation of the nature of the problem and reassurance to patient and her family.
- Hormonal treatment is helpful in patients with recurrent problem or if patient is anemic. Progestogens are usually effective but estrogens can be added in cases with breakthrough bleeding.
- Progestogens therapy alone can be used as it prevents endometrial hyperplasia. Combined estrogen progestogen therapy can also be used. Estrogen alone should not be used as it stimulates endometrial stimulation.
- In adolescents who do not respond to medical therapy occasional diagnostic curettage may be needed to rule out endometrial hyperplasia. In patients who become anemic and have repeated problem, regular hematological investigations should be done to rule out blood dyscrasias.

Fetal Origin of Adult Disease

Panna Choudhury, Tarun Gera

Recent research has suggested that impaired intrauterine growth and development are responsible for several of the major diseases of later life, including coronary heart disease, hypertension, and type 2 diabetes. It has been proposed that alterations in fetal nutrition and endocrine status result in developmental adaptations with consequent changes, sometimes permanent, in the structure, physiology, and metabolism of the individual leading to cardiovascular, metabolic, and endocrine disease in adult life.¹ The process whereby a stimulus or insult at a sensitive or critical period of development has long-term effects is termed programming.²

The initial evidence of the existence of this phenomenon of fetal programming came from animal studies, which showed that alterations in maternal nutrition can have long-term effects on the offspring that are relevant to human cardiovascular disease. For example, feeding pregnant rats a low-protein diet results in lifelong elevation of blood pressure in the offspring.³ Other similar experiments showed notable long-term effects of alterations in maternal nutrition, which included changes in cholesterol metabolism, insulin secretion, and renal development.⁴ The fetal hypothalamus has been implicated as the key site that is programmed by transient changes in prenatal endocrine status.⁴

Fetal Growth and Coronary Heart Disease

At the start of the twentieth century, coronary heart disease became the leading cause of mortality in the Western countries. In some of these countries, the steep rise was followed by an unexplained fall over recent decades that could not be accounted for by changes in adult lifestyle. Simultaneously, the incidence of coronary heart disease has started rising in other parts of the world like China, India, and Eastern Europe, which are not as prosperous and have lower incomes and different lifestyles as

compared to the Western countries. Combined with the limited ability of adult lifestyle risk factors to predict coronary heart disease, this paradox led to the hypothesis that adverse influences in early life might play an important role.

Supportive evidence came from the study by Rose et al⁵ which showed that siblings of patients with coronary heart disease had stillbirth and infant mortality rates that were twice as high as those of control subjects. This led him to conclude that “ischemic heart disease tends to occur in individuals who come from a constitutionally weaker stock”.⁵ Epidemiologic evidence was provided by Forsdahl,⁶ showing that past infant mortality correlated with later arteriosclerotic heart disease in the 20 counties of Norway. These studies seemed to suggest that a poor standard of living in childhood and adolescence was a risk factor for heart disease. Geographic comparisons in England and Wales led to an association between low birth-weight and markedly elevated coronary heart disease death rates.⁷ This led to the postulation of the hypothesis that low-birth-weight babies who survived infancy and childhood might be at increased risk of coronary heart disease as adults.

This hypothesis was then supported by a number of studies. A follow-up study of 15726 men and women born in Hertfordshire, United Kingdom, showed for the first time that those who had low birth weights had relatively high death rates from coronary heart disease in adult life.⁸ Another study, of 1586 men born in Sheffield during 1907–1925, showed the importance of intrauterine growth retardation in comparison to prematurity in determining the increased risk of the disease.⁹ Findings from UK have been replicated in a number of trials all over the world including India.¹⁰ This has led to wide acceptance that low rates of fetal growth are associated with coronary heart disease in later life.

Subsequent studies have found that a wide range of organs and systems may be programmed by the intrauterine environment. These findings are in keeping with the results of experimental studies in animals and suggest that programming reflects a general principle of developmental biology.

High Blood Pressure and Hypertension

A systematic review of 34 studies found a strong association between low birth weight and high blood pressure in prepubertal children and adults.¹¹ Similarly to coronary heart disease, high blood pressure is found in people who were small for gestational age rather than those born prematurely.⁴ Also individuals who were disproportionate (thin or short) at birth also tended to have high blood pressure and a greater risk of hypertension in adult life.⁴

Critics of the hypothesis of 'fetal programming' have often argued that it is the persistence of adverse environmental influences that produces the effects attributed to programming *in utero*. There is, however, little evidence to support this argument. Rather, associations between birth weight and adult blood pressure, for example, were found in each social group and are independent of influences such as smoking, alcohol intake, and obesity in adult life.^{1,4}

Type 2 Diabetes and Insulin Resistance

An association between low birth weight and altered glucose metabolism has been reported in a number of studies.^{4,12-18} The prevalence of type 2 diabetes and impaired glucose tolerance was found to fall progressively between those who were small and those who were large at birth. As for high blood pressure, the associations between birth weight and later glucose tolerance are independent of adult lifestyle influences.¹ Adult obesity does, however, add to the intrauterine effects, such that the highest prevalence of type 2 diabetes and impaired glucose tolerance is seen in people who were small at birth but obese as adults.¹⁸

The mechanism of association between poor intrauterine growth and impaired glucose tolerance may be due to reduction in the number of pancreatic B-cells and a diminished capacity to make insulin.¹⁹ There is stronger evidence that people who were thin at birth tend to be insulin resistant in adulthood and to have metabolic changes suggestive of a bias toward fuel conservation.^{12,20,21} The glucose–insulin–insulin-like growth factor I axis has a key role in stimulating cell division in fetal life.²² Presence of adverse intrauterine environment leads to an adaptive conservation of glucose by reducing growth by inducing insulin resistance in specific tissues, including skeletal muscle. This results in diminished muscle mass and thinness at birth. In adult life, persistence of insulin resistance in skeletal muscle leads to a range of metabolic abnormalities and could underlie the strong association between low

birth weight and thinness at birth and the insulin resistance syndrome in adult life.

Cholesterol Metabolism and Blood Coagulation

Adult men and women whose fetal growth was restricted tended to have high serum concentrations of total cholesterol, LDL cholesterol, apolipoprotein B, fibrinogen, and factor VII.^{4,23} These abnormalities were more pronounced in those who had abnormal body proportions at birth and a short body in relation to their head size, i.e. asymmetric growth retardation. The abdominal circumference at birth seems to be highly predictive of high serum LDL-cholesterol and plasma fibrinogen concentrations in adult life.²³ It has been postulated that poor fetal nutrition and oxygenation leads to cranial redistribution of oxygenated blood away from the trunk to sustain brain metabolism. This impairs the growth of the liver and may underlie permanent abnormalities in the regulation of cholesterol and clotting factors.

The other tissues and organ systems for which there is evidence of programming in humans is summarized in Table 1.²⁴

The evidence cited so far has demonstrated that low birth weight is associated with subsequent development of adult diseases. However, it must be remembered that there are critical specific windows during development, often coincident with periods of rapid cell division, during which a stimulus or insult may have long-lasting consequences on tissue or organ function after birth. Birth

Table 1: Tissues and systems for which there is evidence of programming in humans²⁴

<i>Tissue or system</i>	<i>Examples of programming</i>
Cardiovascular system	Vascular compliance, endothelial function
Respiratory system	Lung volume
Endocrine system	Hypothalamic-pituitary-adrenal axis Glucose-insulin metabolism, growth hormone-IGF-1 axis
Reproductive system	Age at menarche, polycystic ovary syndrome
Central nervous system	Schizophrenia
Skeletal muscle	Insulin resistance, glycolysis during exercise
Bone	Bone mineral content
Kidney	Renin-angiotensin system
Liver	Cholesterol metabolism, fibrinogen and factor VII synthesis
Immune system	Thyroid autoantibodies, IgE concentrations

IGF-1: insulin-like growth factor 1; Ig: immunoglobulin.

weight is only one marker of an adverse fetal environment, and confining studies to this population only may lead to erroneous conclusions. There is emerging evidence that mitochondrial dysfunction and oxidative stress play an important role in the pathogenesis of the fetal origins of adult disease.

Low Birth Weight

It is apparent that the *in utero* environment in which a fetus grows and develops may have long-term effects on subsequent health and survival. Ravelli and colleagues²⁵ in their landmark study of 300,000 men showed that exposure to the Dutch famine of 1944 through 1945 during the first half of pregnancy resulted in significantly higher obesity rates at the age of 19 years. In the previous section we have cited subsequent studies which have demonstrated a relation between low birth weight and the later development of cardiovascular disease, impaired glucose tolerance and other diseases even after adjusting for lifestyle factors, such as smoking, physical activity, occupation, income, dietary habits, and childhood socioeconomic status, and occur independent of the current level of obesity or exercise.²⁶

High Birth Weight

Higher birth weight is associated with higher body mass index (BMI) and increased prevalence of obesity in adult life.²⁷ It is difficult to discern whether it is metabolic programming or establishment of lifestyle behaviors which is responsible for 'tracking' of weight through life. Recent data also suggest that rapid weight gain during infancy is associated with obesity later in childhood, perhaps reflecting a combination of genetically determined catch-up growth and postnatal environmental factors.²⁷

ROLE OF CATCH-UP GROWTH

Catch-up growth can refer to the first 6 to 12 months of life to as late as 2 years after birth and usually refers to realignment of one's genetic growth potential after intrauterine growth retardation (IUGR). The effects of impaired fetal growth are modified by subsequent growth. This led to the second part of the hypothesis proposed by Barker and Hales: the idea of the "thrifty phenotype." As an adaptation to undernutrition in fetal life permanent metabolic and endocrine changes occur which would be beneficial if nutrition remained scarce after birth. If nutrition becomes plentiful, however, these changes predispose to obesity and impaired glucose tolerance. The highest risk for the development of type 2 diabetes is among adults who were born small and became overweight during childhood.²⁸⁻³⁰ Insulin resistance is most prominent in Indian children and in Indian men and women who were born small for gestational age (SGA) but had a high fat mass between the ages of 2 and 12 years.^{28,29} Similar findings were reported

in 10-year-old children in the United Kingdom.³¹ It is likely that accelerated growth confers an additional risk to the growth-retarded fetus.

New Findings from Mechanistic Studies

The 'Barker hypothesis' is increasingly being accepted and has been expanded to other diseases like cognitive functional development, osteoporosis and allergies. The impact of environmental influences on adult disease risk has become more acceptable with elucidation of sound theoretical frameworks of evolutionary biology and epigenetic data that provides molecular mechanisms for the same.³² For instance, epigenetic studies in individuals exposed to the Dutch famine have found decreased methylation in of IGF2 gene.³³ Other investigators have similarly identified six more genes in growth, metabolic and cardiovascular disorders with altered methylation status in fetus exposed to *in utero* deprivation.³⁴ Other mechanisms attributable to nutritional programming of disease include alteration in the cell number/type, impaired HPA axis, impaired mitochondrial activity, free radical damage and altered endocrine and corticoid sensitivity.³⁵ The basic objective of fetal programming is to adjust to an adverse environment. However, if the environment differs in the postnatal period differs from that in the prenatal and early postnatal period it brings various diseases in its wake.

Caveats

These data suggest that low birth weight is associated with glucose intolerance, type 2 diabetes, and cardiovascular disease. The question remains as to whether these associations reflect fetal nutrition or other factors that contribute to birth weight and the observed glucose intolerance. Because of the retrospective nature of the cohort identification, many confounding variables were not always recorded, such as lifestyle, socioeconomic status, education, maternal age, parental build, birth order, obstetric complications, smoking, and maternal health. Maternal nutritional status, directly in the form of diet history or indirectly in the form of BMI, height, and pregnancy weight gain, were usually not recorded. Instead, birth anthropometric measures were used as proxies for presumed under nutrition in pregnancy.

To conclude, childhood onset of adult cardiovascular disease has become a significant public health problem that needs to be addressed globally and individually. Genetic-environment interactions are ubiquitous in human development. It remains to be seen whether better maternal nutrition decreases the incidence of cardiovascular disease in offspring. The final link, of course, will be at the molecular level. Although much progress has been made in the identification and treatment of adult cardiovascular disease, the mechanisms of obesity, hypertension,

atherosclerosis, and diabetes remain to be elucidated, and the changes that take place in an abnormal fetal environment remain poorly understood. The thrifty phenotype also is a paradigm that has stimulated animal as well as human research on fetal growth retardation; its neuroendocrine and metabolic effects; and the possible mechanism by which metabolism, body composition, and growth may be permanently affected. It was widely if not universally accepted by the congress as a model to explain the link between fetal growth retardation and later diseases. Of the existence of that link there is no doubt, and in the 21st century it may matter most in the Indian subcontinent. A recent review has dealt in depth the intrauterine environment that is dramatically impacted by the overall maternal health and the so called "fetal programming" that includes developmental disruption, immediate adaptation, or predictive adaptation which can lead to epigenetic changes affecting a specific organ or overall health.³⁶ Better understanding of the etiology of these disease states will bring with it enhanced preventive and targeted therapies.

An Approach to Management of Rickets

Harish K Pemde, Sandeep Tripathi

AN APPROACH TO MANAGEMENT OF RICKETS

Rickets is generally regarded as the vitamin D deficiency disease. The term rickets evolved from the old English word—wreck, meaning to twist. This twisting or bending of bones was known to physicians since centuries ago and it was gradually found to have more than one cause.¹

Rickets was rampant in north Europe and USA during the early years of the 20th century. Although public health measures have largely corrected this problem, many cases are still reported secondary to preventable nutritional vitamin D deficiency. It is currently a significant problem in developing countries with prevalence of >10 percent among children in Africa. UNICEF has estimated that up to 25 percent of children in China have some evidence of rickets.²

Normal bone growth and mineralization require adequate amount of calcium and phosphate, the two major constituents of the crystalline component of bone. Deficient mineralization can result in rickets and/or osteomalacia. Deficient mineralization at the growth plate causes rickets, whereas impaired mineralization of the bone matrix leads to osteomalacia. They both usually occur together as long as the growth plates are open; only osteomalacia occurs after the growth plates have fused.³

Mineralization defects are classified according to the predominant mineral deficiency. Calcipenic (hypocalcemic) rickets is primarily caused by the calcium deficiency and phosphopenic (hypophosphatemic) rickets is primarily caused by phosphate deficiency.

STAGES OF RICKETS

Clinical manifestations of rickets in children usually occur in the latter half of the first year or in the second year. Rickets is uncommon before the age of three months. It may occur in older children with malabsorption or other systemic disorders. The disease can be divided into three stages:⁴

Stage 1: Osteopenia and subclinical or overt hypocalcemia (usually transitory, and undocumented).

Stage 2: Rising levels of parathyroid hormone (PTH) causes calcium re-absorption from the bones and correction of hypocalcemia. Demineralization of collagen matrix leads to various bone changes and bone pain (mediated by the periosteal sensory pain fibers).

Stage 3: Bone changes becomes more severe and hypocalcemia once again becomes evident.

CLINICAL FEATURES

Rickets can be asymptomatic and is often detected as a chance clinical finding. Its symptoms can range from none to varying degrees of irritability, delay in gross motor development, and bone pain. Clinical findings are related to the involved skeletal sites (Fig. 1).

Head

- Anterior fontanel closure is delayed and may remain open after 18 months.
- Craniotabes (soft skull bones) and flattening of the posterior skull can be seen. Prominence of frontal bones and the major foramen can result in frontal bossing and a prominent sometimes square, forehead (caput quadratum).

Thorax

- *Rachitic rosary:* This consists of enlarged ends of the ribs, resembling beads. These are palpable and visible at the costochondral junction. As a result the sternum can become more prominent, leading to a pigeon breast or pectus carinatum appearance.
- *Harrison groove:* This is a semicircular linear depression in chest wall over the abdomen at the level of the insertion of the diaphragm. This occurs because pliability of ribs increases due to softening.

Fig. 1: Clinical features of rickets

Fig. 2: Radiological features of rickets

Spine

A mild to more pronounced scoliosis can be found.

Pelvis

A prominent promontary can be found and the antero-posterior diameter of the pelvis can shrink as a result of scoliosis. This may cause difficulty during child birth as it persists in girls.

Extremities

Arms

- Greenstick fractures due to concurrent osteomalacia.
- Thickening of wrist at the level of epiphysis if found clinically. However, this is not visible in X-ray, since the lesion consists of cartilage.

Legs

- Bowing of long bones (genu varum) is typical due to weight bearing.
- Anterior bowing of tibia (Saber-shin deformity) may occur.
- Development of knock-knees may occur due to displacement of growth plate due to active disease.
- Identical to the process in wrist, thickening at the level of ankle occurs leading to appearance like double malleoli.

Diagnose of Rickets

The diagnosis of rickets is based on clinical manifestation, characteristic radiological picture and biochemical findings. Biochemical findings are often positive early in course of rickets when radiological feature are not present.

Radiological Findings⁵ (Fig. 2)

The findings are due to, increased uncalcified osteoid in the immature skeleton. The changes of rickets are best visualized at the growth plate of rapidly growing bones. Thus, in the upper limb, the distal ulna is the site that best demonstrates the early signs of impaired mineralization. The metaphysis above and below the knees are the most useful sites in the lower extremities.

A 10 point radiographic scoring system was developed to aid in assessment of the severity of rickets on the basis of knee and wrist findings⁶ (Table 1).

Table 1: Radiological scoring of nutritional rickets⁶		
<i>Wrist</i>	<i>Score both radius and ulna separately</i>	<i>Score</i>
Grade-1	Widened growth plate. Irregular metaphyseal margins, but without concave cupping	1
Grade-2	Metaphyseal concavity with fraying of margins	2
	2 bones × 2 points = 4 points possible	
Knee	Score both femur and tibia separately. Multiply the scores in A by the multiplier in B to get the final score.	
A	Grading based on degree of lucency and widening of zone of provisional calcification.	
Grade-1	Grading based on degree of lucency and widening of zone of provisional calcification.	1
Grade-2	Partial lucency, smooth margin of metaphysis not visible.	2

Cont...

Grade-3	Complete lucency, epiphysis appears widely separated from distal metaphysic.	3
B	Multiplier	
	0.5 = <1 condyle or plateau; 1 = 2 condyle or plateau	
	2 bones × 1 point × 3 points = 6 points possible	
	Maximum 10 points are possible.	

Score the worst affected knee and wrist. See Figure 3. Adapted from reference.⁶

Types of Rickets

The most commonly encountered rickets is the one due to vitamin D deficiency. There may be various causes of vitamin D deficiency and rickets may not be due to vitamin D deficiency alone (Table 2).

Though this list is long, not all the causes are clinically important. Clinically useful causes are:

1. Vitamin D deficiency
2. Vitamin D dependent rickets type 1 (due to decreased 1 α hydroxylase)
3. Vitamin D dependent rickets type 2 (due to end organ resistance)

Table 2: The causes of rickets

S.No.	Category	Causes
1.	Vitamin D deficiency	Dietary deficiency Deficient endogenous synthesis
2.	Mal absorption of vitamin D	Small intestine disease Partial or total gastrectomy Hepatobiliary disease Chronic pancreatic insufficiency
3.	Disorders of vitamin D metabolism	Vitamin D dependent rickets types 1 and 2 Use of anticonvulsants Chronic renal failure
4.	Acidosis	Distal renal tubular acidosis (RTA) Chronic acetazolamide ingestion Chronic ammonium chloride ingestion
5.	Chronic renal failure	
6.	Phosphate depletion	Dietary-low phosphate ingestion Use of nonabsorbable antacids Tumor associated (oncogenic rickets)
7.	Generalized renal tubule disorders	Primary renal Associated with systemic metabolic disorders – Cystinosis – Glycogenosis – Lowe syndrome Systemic disorders with associated renal disease – Inborn errors (Wilson's disease, tyrosinemia) – Acquired-multiple myeloma – Intoxication-cadmium, lead
8.	Primary mineralization defects	Di-phosphonate treatment Fluoride treatment

Table 3: Biochemical parameters in different conditions causing rickets

Type	Vit. D deficient	Vit. D dependent Type-1	Vit. D dependent Type-2	X-linked hypophosphatemia	Hereditary hypophosphatemic rickets with hypercalciurea
Calcium	↓ or N	↓	↓	N	N
Phosphate	↓ or N	↓ or N	↓ or N	↓↓	↓↓
Alkaline phosphatase	↑	↑↑	↑↑	↑	↑
PTH	↑	↑	↑	N	↓ or N
25-(OH)D ₃	↓	N	N	N	N
1,25(OH) ₂ D ₃	↓ or N	↓↓	↑↑	↓ or N	↓
Urine calcium	↓ or N	↓	↓	↓	↑

↑, increased; ↓, decreased; N, normal. Adapted from Reference⁷

4. Vitamin D resistant rickets (X-linked hypophosphatemic rickets)
5. Renal rickets (Rickets with hyperphosphatemia).

Various conditions causing rickets have different combination of abnormalities in biochemical parameters as given in Table 3.

Management of Vitamin D Deficiency Rickets

Treatment of vitamin D deficiency rickets consists of the replacement of deficit plus adequate mineral intake. Two approaches have been used. One is Stross therapy, a method first devised in Europe in the 1930's to prevent rickets in infants and the others, consists of daily administration of high dose vitamin D. Stross therapy involves the single day administration of a large dose of vitamin D 3 lakh to 6 lakh IU given once or in two divided doses over 24 hours either orally or intramuscularly.⁸ Serum levels of 25(OH) D₃ and calcitriol begin to increase within hours. Radiological evidence of healing is visible in one week. If healing is not seen on X-ray plates of bones within 3-4 week, then the above dose is repeated. Cases who respond are further put on 400 units or 10 micrograms of vitamin D per day after the process of healing has started. Biochemically Ca and iP levels increase in serum by day 5 and PTH levels begin to decline. Alkaline phosphatase concentrations remain high for months. Rarely Stross therapy fails or the reaction is delayed, this appears to be related to the presence of intercurrent illness at the time

of administration. Hypercalcemia can occur if the treatment is repeated more than twice a year and has been reported in 34 percent of such case.^{9,10}

The alternative of Stross therapy is daily administration of oral vitamin D at a dose of 2000 to 4000 IU for 2 to 4 weeks followed by 400 IU daily. Radiological and biochemical response are slower by this method and care must be taken to monitor 25(OH) D₃ levels to prevent hypervitaminosis D. Daily therapy needs strict vigil on compliance and follow up for 2-4 months. This makes Stross therapy a preferred mode of treatment. It provides sufficient vitamin D to maintain 25-hydroxy D₃ levels for approximately 3 months.

Approach to a Case of Resistance to Vitamin D

Till the 2nd dose of vitamin D the management of rickets is straightforward, the problem arises when there is no response to the 2nd dose. Now, the cause of vitamin D resistance has to be searched. A basic approach is outlined in Flow chart 1.

Characteristic Features and Management of Vitamin D Resistant Variants of Rickets

Vitamin D Malabsorption

Vitamin D absorption is chylomicron dependent.¹¹ Children with gastrointestinal diseases that interfere with fat absorption and enterohepatic recirculation are at risk for

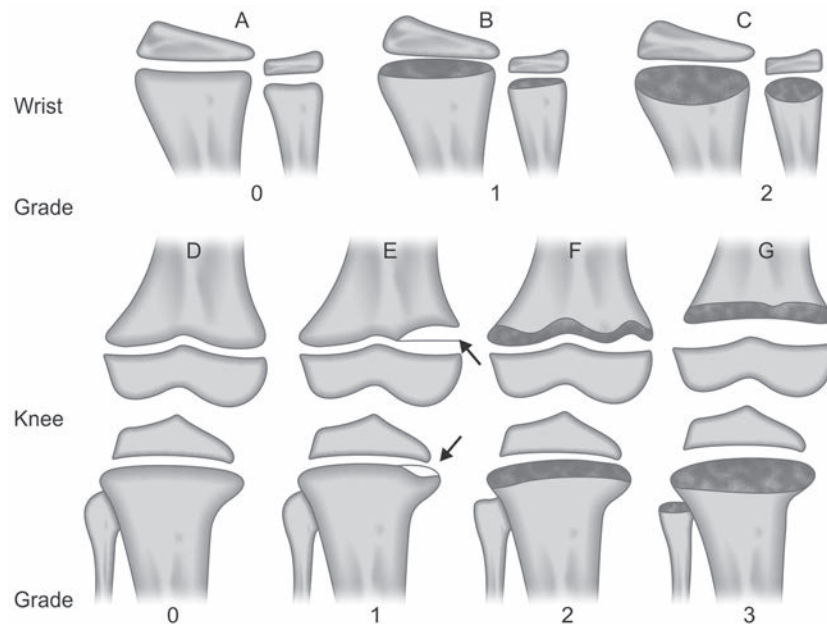

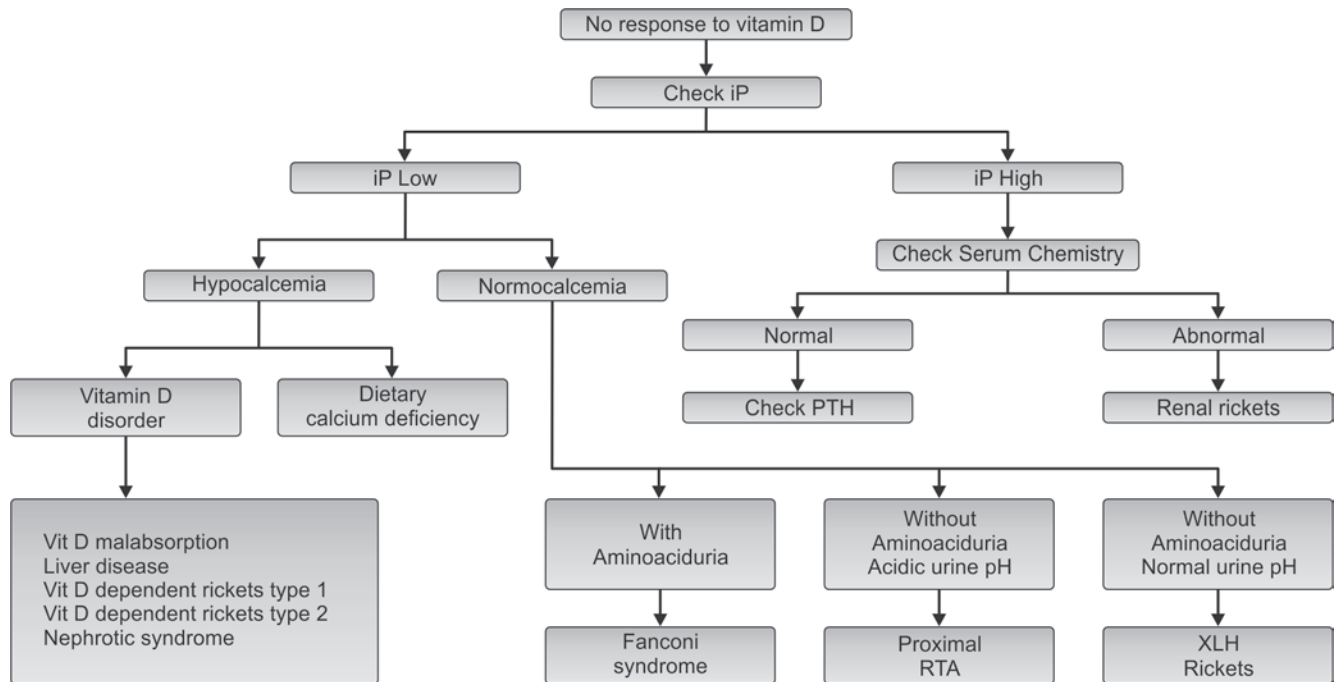

Fig. 3: Radiological scoring for nutritional rickets. A = Normal wrist; B = Irregularity and widening of the growth plate, but without concave cupping; C = Concave metaphyseal cupping and frayed margins; D = A normal knee; E = Only the medial portion of the femoral and tibia metaphyses are affected; F = There is partial lucency of the metaphyses, but the margins are not sharply defined. However, the zone of provisional calcification is not completely lucent and displays some calcification; G = Complete lucency of provisional zone of calcification. The epiphyses appear widely separated from the distal epiphyses. Reproduced with permission from Oxford University Press; reference⁶

Flow chart 1: Outline of diagnosis of vitamin D resistant rickets

developing vitamin D deficiency. These disorders include cholestatic hepatopathies, chronic disease, cystic fibrosis and celiac disease. Parental Stross therapy is indicated.²⁰

Liver Failure

Liver parenchymal cells have a large capacity to produce 25-hydroxy vitamin D and significant hepatic destruction must occur before a deficiency state is reached. Administration of anticonvulsants (phenobarbitone, phenytoin) may cause vitamin D to be shunted to other enzymatic pathways in liver that results in production of polar metabolites that are rapidly excreted. Inborn errors of metabolism causing defective 25-hydroxylation are very rare.¹²

In drug induced rickets correction of vitamin D deficiency is done by Stross therapy and 1000 IU daily of vitamin D supplementation should be given to prevent recurrence of the disorder.¹²

Vitamin D Dependent Rickets Type 1

It is an autosomal recessive disorder manifesting at around 3 to 6 months of age. Enzyme activity of 25(OH)-1 α -hydroxylase is deficient resulting in low levels of 1, 25(OH) D₃, even in presence of hypocalcemia, hypophosphatemia and high parathormone levels. These children develop dental enamel hypoplasia.¹³

For treatment either massive dose of D₃ (2 lakh to 1 million) or low dose of calcitriol 1 to 2 microgram/day are recommended. The treatment has to be continued indefinitely.

Vitamin D Dependent Rickets Type 2

Some cases of vitamin D dependent rickets fail to reverse after treatment with either high dose of vitamin D₃ or calcitriol at 1 to 2 microgram/day. They are labeled as having vitamin D dependent rickets type 2. They have either:¹⁴

1. Reduced or absent 1,25(OH)₂ D₃ binding to the human vitamin D nuclear receptor.
2. Decreased affinity of this receptor for DNA so that transcription does not occur.
3. Defective nuclear translocation or retention.

This condition is particularly common among children of first cousin marriages. Some patients have short stature and alopecia totalis and ectodermal defects (oligodontia, milia and epidermal cyst).¹⁵ This condition may be reversed by administration of 15 to 30 micrograms/day of 1, 25(OH)₂ D.

X-Linked Hypophosphatemic Rickets (Vitamin D Resistant Rickets)

It is the most common form of non-nutritional form of rickets.¹³ Usual mode of inheritance is X-linked dominant, so mothers of affected sons are also affected though with milder manifestations. The defects involve in proximal tubular reabsorption of phosphate and in conversion of 25(OH) D to 1, 25(OH) D. So oral phosphate supplementation alone cannot correct bone disease, the correction requires 1, 25(OH)₂ D therapy.

Clinical features: Age of onset is usually after 6 to 12 months of age. Children present with bowing of lower extremities.

Tetany is not present and the profound myopathy, rachitic rosary and Harrison groove characteristic of calcium deficient rickets are not present. Maximum manifestations are in lower extremities and short stature. Genu varum is more common than genu valgum.¹⁵ Pulp deformities and lesions of intraglobular dentin are characteristic tooth anomalies. Enamel defects are found only occasionally (calcium deficient rickets usually results in enamel defects).

Lab findings: Radiological findings are similar to calcopenic rickets. Biochemically patients have normal or slightly reduced calcium level, a moderately reduced serum phosphate (1.5-3 mg/dl) elevated alkaline phosphatase and no evidence of secondary hyperparathyroidism. Urinary phosphate excretion despite hypophosphatemia is large indicating a defect in tubule phosphate absorption. Aminoaciduria, bicarbonaturia, glycosuria and kaliurea are not found differentiating the condition from generalized tubular disorders.¹⁴

Treatment: Oral phosphate supplements coupled with vitamin D analogs.¹⁴

Phosphate: Young children need 0.5 to 1 gm/day and older children need 1 to 4 g/day. Phosphate is given as Joulie's solution (30.5 mg of phosphate/ml). It has to be given every 4 hours as urinary excretion of phosphate is constant. The main side effect of oral phosphate is diarrheas.

Calcitriol: 50 to 65 ng/kg/day or vitamin D₂ at 2000 IU/kg/day. The side effect is hypercalciurea and nephrocalcinosis, which can be reduced by hydrochlorthiazide.

Renal Rickets

Many factors contribute to osteodystrophy in chronic renal failure including:¹⁵

- Decreased synthesis of 1,25 (OH)₂ D₃.
- Hyperphosphatemia—which causes a reciprocal decrease in serum calcium, which stimulates parathyroids. Hyperparathyroidism causes osteitis fibrosa cystica.
- Metabolic acidosis.

Clinical features depend on age of patient and duration of disease. Infants show features of rickets with delayed development. In older child genu valgum and ulnar deviation of wrist, scoliosis, compression fractures of vertebrae. Pathological fractures of long bones, etc.

Treatment

- Restrict high phosphate foods such as dairy products, chocolate, dark colored sodas.
- Calcium containing phosphate binders as calcium carbonate and acetate. Usual starting dose is 500 to 1250 mg of calcium carbonate or acetate with each meal.
- 1, 25 (OH)₂ D₃ at 0.25 to 1 microgram/day.

Preparations of Vitamin D Available in India

The available preparations are:¹⁶

1. *Calciferol (ergocalciferol, vitamin D₂)*: As solution in oil, filled in gelatin capsules 25,000 and 50,000 IU caps.
2. *Cholecalciferol (vitamin D₃)*: As granules for oral ingestion and oily solution for IM injection. Arachitol 3 lakh IU (7.5 mg) and 6 lakh IU (15 mg) per ml. Calcirol 60,000 IU in 1 gm granules.
3. *Calcitriol (1, 25 (OH)₂ D₃)*: 0.25 to 1 microgram sachets.
4. *Alfacalcidol*: By passes the renal activation step. Useful in renal rickets 0.25 to 1 microgram sachets.
5. *Dihydrotachysterol (DHT)*: Synthetic analog of vitamin D₂. Directly mobilizes calcium from bones. Does not require PTH dependent activation in kidneys-useful in hypoparathyroidism and renal bone disease. Dose 0.25 to 0.5 mg/day.

INTRODUCTION

Zinc is a trace element of vital importance for the normal functioning of the reproductive, neurologic, immune, dermatologic and gastrointestinal systems. It is a constituent of various metalloenzymes including transferases, hydrolases, ligases, lyases, isomerases and oxidoreductases which help in nucleic acid and protein synthesis and degradation. Zinc chelates with the amino acids cysteine and histidine, forming 'zinc fingers' that are important for protein transcription. Processes that are regulated by zinc include expression of the metallothionein gene, apoptosis and synaptic signaling. Zinc deficiency is one of the ten biggest factors contributing to burden of disease in developing countries with high mortality.¹ With the emerging evidence of the anti-infective potential of zinc in preventing and shortening diarrhea, in combating respiratory infections, and even in reducing mortality in malaria, this trace element is currently the center of enormous interest.

ZINC REQUIREMENT AND DEFICIENCY

The current recommended dietary allowance (RDA) for zinc is listed in Table 1.² For infants aged 0 to 6 months, the values reflect adequate intake (AI) for zinc that is equivalent to the mean intake of zinc in healthy breast fed infants. The optimal source of zinc is from animal sources, such as beef, lamb and oysters. Exclusively breast-fed infants are usually able to get an adequate amount of zinc from breastfeeding during the first six months of life. However, infants who are small for their gestational age and premature infants may benefit from zinc supplementation in addition to the zinc they receive from breastfeeding. During the second six months of life when complementary foods are introduced, the risk for zinc deficiency increases because zinc is commonly the most deficient nutrient in complementary food mixtures fed to infants

during weaning.³ As more and more single-nutrient intervention research is conducted, it is becoming clear that zinc-responsive deficits in body composition are widespread in developing countries. Populations in South East Asia and sub-Saharan Africa are at greatest risk of zinc deficiency; zinc intakes are inadequate for about a third of the population and stunting affects 40 percent of preschool children.⁴ The deficiency has been attributed to a low dietary intake of zinc-rich foods, high consumption of cereal grains and legumes, which contain inhibitors

Table 1: Recommended dietary allowances (RDAs) for zinc

Age	Recommended dietary allowance
0–6 months	2 mg*
7–12 months	3 mg
1–3 years	3 mg
4–8 years	5 mg
9–13 years	8 mg
14–18 years	
Male	11 mg
Female	9 mg
19+ years	
Male	11 mg
Female	8 mg
Pregnancy	
<18 years	12 mg
≥19 years	11 mg
Lactation	
<18 years	13 mg
≥19 years	12 mg

* Adequate intake (AI)

of zinc absorption and excess fecal losses of zinc due to recurrent episodes of diarrhea.

Serum or plasma zinc is the best available biomarker of the risk of zinc deficiency in populations. As serum zinc does not necessarily reflect individual zinc status, presently the use of this indicator for diagnosis and treatment of individuals is not recommended. A joint WHO/UNICEF/IAEA/IZiNCG expert group recommended a serum zinc cutoff of 65 µg/dl (9.9 µmol/L) for identifying zinc deficiency in populations for children aged between two to ten years.^{5,6} Further, the group concluded that the risk of zinc deficiency is considered to be of public health concern when the prevalence of low serum zinc concentrations is greater than 20 percent. Amongst the functional outcomes, height- or length-for-age is the parameter of choice for estimating zinc deficiency in populations.

A recent cross sectional study from five states of India reported an overall prevalence of zinc deficiency amongst children 6 to 60 months of age as 43.8 percent.⁷ The prevalence of zinc deficiency was highest in Orissa (51.3%), followed by Uttar Pradesh (48.1%), Gujarat (44.2%), Madhya Pradesh (38.9%) and Karnataka (36.2%).⁷ Studies from other regions of India and other developing countries also report zinc deficiency of sufficient magnitude to be a significant public health problem.

ROLE OF ZINC IN INFECTIONS

Zinc is essential for the formation and function of immune system. Zinc deprivation results in impairment of macrophage and T cell activity as well as thymic atrophy and reduced viability of thymocytes, thus compromising the cell mediated immunity. The potential anti-infective benefit of zinc is also mediated via stabilization of the epithelial barrier as well as alterations in the balance of T helper cell and TH1 and TH2 cytokines.

Childhood Diarrhea

A large number of randomized controlled trials (RCTs) have established the importance of zinc in the treatment of acute and persistent diarrhea in under-five children. Zinc supplementation in children in developing countries is associated with a substantial reduction in the rates of diarrhea, according to a pooled analysis by the Zinc Investigators' Collaborative Group.⁸ The group analyzed ten RCTs from nine developing countries. The studies assessed the effects of oral zinc in apparently healthy children younger than 5 years. There were seven continuous trials (in which 1-2 times the RDA of zinc was given 5-7 times per week), and three short-course trials (2-4 times the RDA daily for 2 weeks). For the zinc-supplemented children compared with the control group in the continuous trials, the pooled ORs for diarrheal incidence and prevalence were 0.82 (95% CI 0.72 to 0.93) and 0.75 (95% CI 0.63 to 0.88), respectively. In the short-course trials the

OR for the effects of zinc on diarrheal incidence (OR 0.89, 95% CI 0.62 to 1.28) and prevalence (OR 0.66, 95% CI 0.52 to 0.83) were similar to those in the continuous trials. No significant differences were seen between short and continuous courses.

In a pooled analyses of RCTs of the effects of supplementary oral zinc in children aged <5 y with acute or persistent diarrhea,⁹ zinc-supplemented children had a 15 percent lower probability of continuing diarrhea on a given day (95% CI: 5%, 24%) in the acute-diarrhea trials and a 24 percent lower probability of continuing diarrhea (95% CI: 9%, 37%) and a 42 percent lower rate of treatment failure or death (95% CI: 10%, 63%) in the persistent-diarrhea trials.⁹ In none of the subgroup analyses were the 2 subgroups of each pair significantly different from each other; however, in persistent diarrhea there tended to be a greater effect in subjects aged <12 mo, who were male, or who had wasting or lower baseline plasma zinc concentrations.

In the most exhaustive systematic review from the Cochrane group¹⁰ (Table 2) examining eighteen trials enrolling 6165 participants, zinc resulted in a shorter diarrhea duration (MD -12.27 h, 95% CI -23.02 to -1.52 h; 2741 children, 9 trials), and less diarrhea at day three (RR 0.69, 95% CI 0.59 to 0.81; 1073 children, 2 trials), day five (RR 0.55, 95% CI 0.32 to 0.95; 346 children, 2 trials), and day seven (RR 0.71, 95% CI 0.52 to 0.98; 4087 children, 7 trials). Zinc also reduced the duration of persistent diarrhea (MD -15.84 h, 95% CI -25.43 to -6.24 h; 529 children, 5 trials). No trial reported serious adverse events, but vomiting was more common in zinc-treated children with acute diarrhea (RR 1.71, 95% CI 1.27 to 2.30; 4727 children, 8 trials).

Acute Respiratory Infections

Owing to its benefit in treating childhood diarrhea, some recent trials tried to evaluate the role of zinc in treatment and prevention of pneumonia. A Cochrane review¹¹ of four randomized controlled trials (3267 children aged 2-35 months) showed that zinc supplementation in addition to standard antibiotic therapy in children with severe and nonsevere pneumonia failed to show a statistically significant effect on clinical recovery (risk ratio (RR) 1.02; 95 percent confidence interval (CI) 0.93 to 1.11). Similarly, zinc supplementation in children with severe pneumonia did not show a statistically significant effect on clinical recovery measured as resolution of tachypnea (respiratory rate >50 breaths per minute) (RR 1.13; 95% CI 0.82 to 1.57) and cessation of chest in-drawing (RR 1.08; 95% CI 0.88 to 1.31) as compared to the control group. Zinc supplementation in children with severe pneumonia also showed a nonsignificant effect on the duration of hospitalization stay as compared to the control (RR 1.04; 95% CI 0.89 to 1.22). The review concluded that there is no sufficient evidence to recommend the use of zinc as an

Table 2: Systematic reviews of zinc supplementation in various pediatric conditions

<i>Disease/condition</i>	<i>Author year (Ref)</i>	<i>Characteristics of included trials</i>	<i>Number of trials/participants</i>	<i>Results</i>
Treatment of acute and persistent diarrhea	Lazzerini M et al. 2008 ¹⁰	Randomized controlled trials comparing oral zinc (≥ 5 mg/d) with placebo in children aged one month to five years with acute or persistent diarrhea, including dysentery.	Eighteen trials enrolling 6165 participants	In acute diarrhea, zinc reduced the duration (MD -12.27 h, 95% CI -23.02 to -1.52 h; 2741 children, 9 trials), and less diarrhea at day three (RR 0.69, 95% CI 0.59 to 0.81; 1073 children, 2 trials), day five (RR 0.55, 95% CI 0.32 to 0.95; 346 children, 2 trials), and day seven (RR 0.71, 95% CI 0.52 to 0.98; 4087 children, 7 trials). The four trials (1458 children) that reported on diarrhea severity used different units and time points, and the effect of zinc was less clear. Zinc also reduced the duration of persistent diarrhea (MD -15.84 h, 95% CI -25.43 to -6.24 h; 529 children, 5 trials). No trial reported serious adverse events, but vomiting was more common in zinc-treated children with acute diarrhea (RR 1.71, 95% CI 1.27 to 2.30; 4727 children, 8 trials).
Treatment of pneumonia	Haider BA et al. 2011 ¹¹	RCTs evaluating supplementation of zinc as an adjunct to antibiotics for pneumonia in children aged two to 59 months.	Four trials with 3267 children.	Zinc supplementation in addition to standard antibiotic therapy in children with severe and nonsevere pneumonia failed to show a statistically significant effect on clinical recovery (risk ratio (RR) 1.02; 95% confidence interval (CI) 0.93 to 1.11). Similarly, zinc supplementation did not show a statistically significant effect on clinical recovery measured as resolution of tachypnea (respiratory rate > 50 breaths per minute) (RR 1.13; 95% CI 0.82 to 1.57) and cessation of chest indrawing (RR 1.08; 95% CI 0.88 to 1.31) as compared to the control group. Zinc supplementation had no effect on the duration of severe pneumonia related hospitalization as compared to the control (RR 1.04; 95% CI 0.89 to 1.22).
Prevention of pneumonia	Lassi ZS et al. 2010 ¹²	Randomized controlled trials evaluating supplementation of zinc in children aged 2-59 months of age.	Six trials and 7850 participants	Zinc supplementation reduced the incidence of pneumonia by 13% (risk ratio (RR) 0.87; 95% confidence interval (CI) 0.81 to 0.94, fixed-effect, six studies) and prevalence of pneumonia by 41% (RR 0.59; 95% CI 0.35 to 0.99, random-effects, one study).
Common cold	Singh M et al. 2011 ¹³	Randomized, double-blind, placebo-controlled trials using zinc for at least five consecutive days to treat, or for at least five months to prevent the common cold.	13 therapeutic trials (966 participants) and two preventive trials (394 participants).	Intake of zinc was associated with a significant reduction in the duration (standardized mean difference (SMD) -0.97; 95% confidence interval (CI) -1.56 to -0.38) ($P = 0.001$), and severity of common cold symptoms (SMD -0.39; 95% CI -0.77 to -0.02) ($P = 0.04$). There was a significant difference between the zinc and control group for the proportion of participants symptomatic after seven days of treatment (OR 0.45; 95% CI 0.2 to 1.00) ($P = 0.05$). The incidence rate ratio (IRR) of developing a cold (IRR 0.64; 95% CI 0.47 to 0.88) ($P = 0.006$), school absence ($P = 0.0003$) and prescription of antibiotics ($P < 0.00001$) was lower in the zinc group. Overall adverse events (OR 1.59; 95% CI 0.97 to 2.58) ($P = 0.06$), bad taste (OR 2.64; 95% CI 1.91 to 3.64) ($P < 0.00001$) and nausea (OR 2.15; 95% CI 1.44 to 3.23) ($P = 0.002$) were higher in the zinc group.
Pregnancy outcome	Mahomed K et al. 2007 ¹⁴	Randomized or quasi-randomized trials of zinc supplementation in pregnancy.	17 RCTs involving over 9000 women and their babies.	Zinc supplementation resulted in a small but significant reduction in preterm birth (relative risk (RR) 0.86, 95% confidence interval (CI) 0.76 to 0.98 in 13 RCTs; 6854 women). This was not accompanied by a similar reduction in numbers of babies with low birthweight (RR 1.05 95% CI 0.94 to 1.17; 11 studies of 4941 women). No significant differences were seen between the zinc and no zinc groups for any of the other primary maternal or neonatal outcomes, except for a small effect favoring zinc for cesarean section (four trials with high heterogeneity) and for induction of labor in a single trial. No differing patterns were evident in the subgroups of women with low versus normal zinc and nutrition levels or in women who complied with their treatment versus those who did not.
Prevention of morbidity and mortality in LBW infants	Gulani A et al. 2011 ¹⁵	Randomized or quasi-randomized trials of zinc supplementation (orally to provide at least 1 RDA of elemental zinc for at least 14 d) in LBW neonates, with individual or cluster allocation.	Three RCTs	There was no evidence of a reduced risk of mortality (1 trial, RR=1.11; 95% CI 0.57 to 2.18 at one year), hospitalization rate (1 trial, odds ratio 1.10; 95% CI 0.87 to 1.39), acute respiratory infection (1 trial), or diarrhea (2 trials). There was no evidence of an increase in weight (3 trials) or height (2 trials) at either 6 months or one year of age, or of an increased risk of vomiting following zinc supplementation. Serum zinc levels at the end of intervention were significantly higher in the supplemented group (2 trials).

adjunct to standard antibiotic therapy for pneumonia in children aged two to 35 months (Table 2).

Regarding role of zinc in preventing pneumonia, the Cochrane systematic review¹² of six RCTs (7850 participants) showed that zinc supplementation reduced the incidence of pneumonia by 13 percent (risk ratio (RR) 0.87; 95 percent confidence interval (CI) 0.81 to 0.94, fixed-effect, six studies) and prevalence of pneumonia by 41 percent (RR 0.59; 95% CI 0.35 to 0.99, random-effects, one study).

The Cochrane review of zinc supplementation in preventing or treating common cold¹³ documented a significant reduction in the duration and severity of common cold symptoms (Table 2). There was a significant difference between the zinc and control group for the proportion of participants symptomatic after seven days of treatment but the adverse effect profile of participants given zinc was not favorable.

Overall, there seems to be some role of zinc in prevention of acute respiratory infections. However, there is no sufficient evidence to recommend its supplementation routinely during the episode.

Malaria

The results of zinc supplementation on the severity and outcome of malaria are conflicting. In a study conducted in Papua New Guinea, a total of 274 preschool children aged 6 to 60 months were given 10 mg elemental zinc (n = 136) or placebo (n = 138) for 6 days a week for 46 weeks.¹⁶ Zinc supplementation resulted in a 38 percent (95% CI 3-60, P = 0.037) reduction in *Plasmodium falciparum* health center-based episodes. Episodes accompanied by any parasitemia were also reduced by 38 percent (95% CI 5-60, P = 0.028). There was no evidence of the effects of zinc on *Plasmodium vivax* morbidity or on health center attendance for causes other than *P. falciparum*. The Zinc Against Plasmodium Study Group evaluated the therapeutic effect of zinc given as an adjuvant to standard therapy during acute malaria in a large double-blind, randomized placebo-controlled clinical trial across 5 countries in Africa and concluded that zinc does not appear to provide a beneficial effect in the treatment of acute, uncomplicated falciparum malaria in preschool children.¹⁷ A trial in Burkina Faso also did not find any reduction in episodes of falciparum malaria among children who received daily supplementation with 10 mg zinc for six months.¹⁸ A recent epidemiological analysis concluded that preventive zinc supplementation has no effect on malaria specific mortality (RR = 0.90; 95% CI: 0.77, 1.06) or incidence of malaria (RR = 0.92; 95 % CI 0.82-1.04).

ZINC AND GROWTH

Zinc plays a critical role in the cellular growth and differentiation. Multiple studies have been carried out to assess

the effect of zinc supplementation on children's growth. The results of these studies are inconsistent, and the factors responsible for these varied outcomes are unknown. In a meta-analysis involving 33 studies, zinc supplementation produced highly significant, positive responses in height and weight increments, with effect sizes of 0.350 (95% CI: 0.189, 0.511) and 0.309 (0.178, 0.439), respectively.¹⁹ There was no significant effect of zinc on weight-for-height indexes (weighted mean effect size: -0.018 (-0.132, 0.097)). Zinc supplementation caused a large increase in the children's serum zinc concentrations, with an effect size of 0.820 (0.499, 1.14). Growth responses were greater in children with low initial weight-for-age z scores and in those aged >6 months with low initial height-for-age z scores. The authors concluded that interventions to improve children's zinc nutriture should be considered in populations at risk of zinc deficiency, especially where there are elevated rates of underweight or stunting and that the population mean serum zinc concentration is a useful indicator of the successful delivery and absorption of zinc supplements in children. However, a subsequent trial in Burkina Faso (709 children aged 6-31 months) has shown no effect of zinc supplementation on growth where similar range of doses of zinc was used even though the supplementation resulted in an increased serum zinc level.²⁰

Zinc supplementation given during pregnancy also does not result in a significant benefit in terms of infant's birth weight¹⁴ or growth (Table 2). Similarly, there is no evidence of neonatal zinc supplementation in terms of infant's weight (3 trials) or height (2 trials) at either 6 months or one year of age¹⁵ (Table 2).

ZINC AND DEVELOPMENT

Zinc is concentrated in the synaptic vesicles of glutamatergic neurons found primarily in the forebrain. During nerve conduction, zinc is released into postsynaptic neurons, serving as a neurotransmitter. Because zinc is considered to be essential for nucleic acid and protein synthesis, zinc deficiency may interfere with these processes and hence compromise subsequent development.

In studies assessing the effect of zinc supplementation on activity, the supplemented group demonstrated increased activity.^{21,22} Improvement in developmental status of very low-birth-weight infants has also been reported after zinc supplementation.²³ However, three studies found no impact of zinc on motor development.²⁴⁻²⁶ Of the four studies that examined mental development in infants and toddlers, three found no impact of zinc supplementation²³⁻²⁵ and one found that zinc-supplemented children had lower scores than control children.²⁶ Among school-age children, one study found no impact of zinc supplementation on cognitive performance²⁷ and two found a beneficial impact of neuropsychological processes,

specifically reasoning.^{28,29} The evidence linking zinc deficiency to children's cognitive and motor functioning lacks a clear consensus, highlighting the need for additional research.

Nutrient Cointerventions with Zinc

Kikafunda et al found that children from the school with the highest socioeconomic status, and therefore a better nutritional background, responded significantly in weight gain to zinc supplementation whereas the children from the poorer schools did not; indicating that zinc was the limiting nutrient in the nutrition of the children with relatively better nutritional status, whereas those with poorer nutritional status were deficient in other nutrients that limited the response in zinc supplementation.³⁰ Sandstead et al conducted a zinc supplementation trial in Chinese children and found that the knee-height increase was significantly greater in the zinc-plus-micronutrients group than in the zinc-alone group.²⁹

It is likely that different effects will be seen when zinc is given in supplemental doses if an individual (1) is without any micronutrient deficits, (2) is uniquely zinc deficient, or (3) has multiple micronutrient deficiencies. This will lead to heterogeneous responses to zinc in free-living populations because all three conditions are likely to coexist.

PROGRAMMATIC ISSUES

As zinc deficiency is a significant public health problem in developing countries, including India, interventions to improve population zinc status are recommended. Supplementation of zinc for 14 days during an episode of acute diarrhea is one such approach due to simultaneous documented benefit in reducing the severity and duration of disease. WHO, UNICEF and Indian Academy of Pediatrics recommend that a daily dose of 20 mg of elemental zinc for children older than 6 months, and 10 mg for children aged 2 months to 6 months should be started as soon as diarrhea starts and continued for a total period of 14 days.³¹ Zinc supplementation is also recommended as part of routine, standard case management in persistent diarrhea and in those with severe malnutrition. Further evidence is required for qualifying its use in treatment of pneumonia and malaria; the use should be discouraged outside research settings.

Tackling zinc deficiency in isolation, however, is inappropriate. In particular, it is important to avoid any further fragmentation of health interventions by creating an additional zinc program. The strategies to combat zinc deficiency must focus on dietary interventions rather than a magic bullet approach. Fluctuation in the status of one micronutrient may alter the metabolism of the other, with functional consequences on the health of the individual, especially in populations with borderline nutriture.³² Medicinal zinc should be perceived only as

a short-term solution in the conditions where it has a documented benefit. Food technology research should be encouraged to identify and assess the feasibility of zinc fortification of candidate foods including complementary diets. Improvement in the quality and quantity of diet should be relied upon as long term strategies to combat zinc deficiency.⁶

Vitamin A and its Controversies

Neha Rastogi, Anupam Sachdeva

INTRODUCTION

Vitamin A (retinol) is an essential nutrient needed in small amounts by humans for the normal functioning of the visual system; growth and development; and maintenance of epithelial cellular integrity, immune function, and reproduction. These dietary needs for vitamin A are normally provided for as preformed retinol (mainly as retinyl ester) and provitamin A carotenoids.

OVERVIEW OF VITAMIN A METABOLISM

Preformed vitamin A in animal foods occurs as retinyl esters of fatty acids in association with membrane-bound cellular lipid and fat-containing storage cells. Provitamin A carotenoids in foods of vegetable origin are also associated with cellular lipids but are embedded in complex cellular structures such as the cellulose-containing matrix of chloroplasts or the pigment-containing portion of chromoplasts. Normal digestive processes free vitamin A and carotenoids from food matrices, which is a more efficient process from animal than from vegetable tissues. Retinyl esters are hydrolysed and the retinol and freed carotenoids are incorporated into lipid-containing, water-miscible micellar solutions. Products of fat digestion (e.g. fatty acids, monoglycerides, cholesterol, and phospholipids) and secretions in bile (e.g. bile salts and hydrolytic enzymes) are essential for the efficient solubilization of retinol and especially for solubilization of the very lipophilic carotenoids (e.g. α - and β carotene, β -cryptoxanthin, and lycopene) in the aqueous intestinal milieu. Micellar solubilization is a prerequisite to their efficient passage into the lipid rich membrane of intestinal mucosal cells (i.e. enterocytes).¹⁻³ Diets critically low in dietary fat (under about 5-10 g daily)⁴ or disease conditions that interfere with normal digestion and absorption leading to steatorrhea (e.g. pancreatic and liver diseases

and frequent gastroenteritis) can therefore impede the efficient absorption of retinol and carotenoids. Retinol and some carotenoids enter the intestinal mucosal brush border by diffusion in accord with the concentration gradient between the micelle and plasma membrane of enterocytes. Some carotenoids pass into the enterocyte and are solubilized into chylomicrons without further change whereas some of the provitamin A carotenoids are converted to retinol by a cleavage enzyme in the brush border.³ Retinol is trapped intracellularly by re-esterification or binding to specific intracellular binding proteins. Retinyl esters and unconverted carotenoids together with other lipids are incorporated into chylomicrons, excreted into intestinal lymphatic channels, and delivered to the blood through the thoracic duct.²

Tissues extract most lipids and some carotenoids from circulating chylomicrons, but most retinyl esters are stripped from the chylomicron remnant, hydrolysed, and taken up primarily by parenchymal liver cells. If not immediately needed, retinol is re-esterified and retained in the fat-storing cells of the liver (variously called adipocytes, stellate cells, or Ito cells). The liver parenchymal cells also take in substantial amounts of carotenoids. Whereas most of the body's vitamin A reserve remains in the liver, carotenoids are also deposited elsewhere in fatty tissues throughout the body.¹ Usually, turnover of carotenoids in tissues is relatively slow, but in times of low dietary carotenoid intake, stored carotenoids are mobilized. A recent study in one subject using stable isotopes suggests that retinol can be derived not only from conversion of dietary provitamin carotenoids in enterocytes—the major site of bioconversion—but also from hepatic conversion of circulating provitamin carotenoids.⁵ The quantitative contribution to vitamin A requirements of carotenoid converted to retinoids beyond the enterocyte is unknown.

Following hydrolysis of stored retinyl esters, retinol combines with a plasma-specific transport protein, retinol-binding protein (RBP). This process, including synthesis of the unoccupied RBP (apo-RBP), occurs to the greatest extent within liver cells but it may also occur in some peripheral tissues. The RBP-retinol complex (holo-RBP) is secreted into the blood where it associates with another hepatically synthesized and excreted larger protein, transthyretin. The transthyretin-RBP-retinol complex circulates in the blood, delivering the lipophilic retinol to tissues; its large size prevents its loss through kidney filtration.¹ Dietary restriction in energy, proteins, and some micronutrients can limit hepatic synthesis of proteins specific to mobilization and transport of vitamin A. Altered kidney functions or fever associated with infections (e.g. respiratory infections⁶ or diarrhea⁷) can increase urinary vitamin A loss.

Holo-RBP transiently associates with target tissue membranes, and specific intracellular binding proteins then extract the retinol. Some of the transiently sequestered retinol is released into the blood unchanged and is recycled (i.e. conserved).^{1,8} A limited reserve of intracellular retinyl esters is formed that subsequently can provide functionally active retinol and its oxidation products (i.e. isomers of retinoic acid) as needed intracellularly. These biologically active forms of vitamin A are associated with specific cellular proteins which bind with retinoids within cells during metabolism and with nuclear receptors that mediate retinoid action on the genome.⁹ Retinoids modulate the transcription of several hundreds of genes.¹⁰⁻¹² In addition to the latter role of retinoic acid, retinol is the form required for functions in the visual¹³ and reproductive systems¹⁴ and during embryonic development.¹⁵

Holo-RBP is filtered into the glomerulus but recovered from the kidney tubule and recycled. Normally vitamin A leaves the body in urine only as inactive metabolites resulting from tissue utilization and in bile secretions as potentially recyclable active glucuronide conjugates of retinol.⁸ No single urinary metabolite has been identified which accurately reflects tissue levels of vitamin A or its rate of utilization. Hence, at this time urine is not a useful biological fluid for assessment of vitamin A nutriture.

BIOCHEMICAL MECHANISMS FOR VITAMIN A FUNCTIONS

Vitamin A functions at two levels in the body. The first is in the visual cycle in the retina of the eye; the second is in all body tissues where it systemically maintains the growth and soundness of cells. In the visual system, carrier bound retinol is transported to ocular tissue and to the retina by intracellular binding and transport proteins. Rhodopsin, the visual pigment critical to dim-light vision, is formed in rod cells after conversion of all-trans-retinol to retinaldehyde, isomerization to the

11-cis-form, and binding to opsin. Alteration of rhodopsin through a cascade of photochemical reactions results in the ability to see objects in dim light.¹³ The speed at which rhodopsin is regenerated is related to the availability of retinol. Night blindness is usually an indicator of inadequate available retinol, but it can also be due to a deficit of other nutrients that are critical to the regeneration of rhodopsin, such as protein and zinc, and to some inherited diseases, such as retinitis pigmentosa. The growth and differentiation of epithelial cells throughout the body are especially affected by vitamin A deficiency (VAD). In addition, goblet cell numbers are reduced in epithelial tissues and as a consequence, mucous secretions (with their antimicrobial components) diminish. Cells lining protective tissue surfaces fail to regenerate and differentiate, hence they flatten and accumulate keratin. Both factors—the decline in mucous secretions and loss of cellular integrity—reduce the body's ability to resist invasion from potentially pathogenic organisms. Pathogens can also compromise the immune system by directly interfering with the production of some types of protective secretions and cells.¹¹ Classical symptoms of xerosis (drying or non-wetability) and desquamation of dead surface cells as seen in ocular tissue (i.e. xerophthalmia) are the external evidence of the changes also occurring to various degrees in internal epithelial tissues. Current understanding of the mechanism of vitamin A action within cells outside the visual cycle is that cellular functions are mediated through specific nuclear receptors. Binding with specific isomers of retinoic acid (i.e. all trans- and 9-cis-retinoic acid) activates these receptors. Activated receptors bind to DNA response elements located upstream of specific genes to regulate the level of expression of those genes.¹² These retinoid-activated genes regulate the synthesis of a large number of proteins vital to maintaining normal physiologic functions. There may, however, be other mechanisms of action that are as yet undiscovered.¹⁰

DEFINITION OF VITAMIN A DEFICIENCY

VAD is not easily defined. World Health Organization defines it as tissue concentrations of vitamin A low enough to have adverse health consequences even if there is no evidence of clinical xerophthalmia.¹⁶ In addition to the specific signs and symptoms of xerophthalmia and the risk of irreversible blindness, nonspecific symptoms include increased morbidity and mortality, poor reproductive health, increased risk of anemia, and contributions to slowed growth and development. However, these nonspecific adverse effects may be caused by other nutrient deficits as well, making it difficult to attribute non-ocular symptoms specifically to VAD in the absence of biochemical measurements reflective of vitamin A status.¹⁶

DIETARY SOURCES OF VITAMIN A

Preformed vitamin A is found almost exclusively in animal products, such as human milk, glandular meats, liver and fish liver oils (especially), egg yolk, whole milk, and other dairy products.¹⁶ Provitamin A carotenoids are found in green leafy vegetables (e.g. spinach, amaranth, and young leaves from various sources), yellow vegetables (e.g. pumpkins, squash, and carrots), and yellow and orange non-citrus fruits (e.g. mangoes, apricots, and papayas).

INDICATORS OF VITAMIN A DEFICIENCY

Clinical Indicators of Vitamin A Deficiency

The term xerophthalmia encompasses the clinical spectrum of ocular manifestations of VAD, from milder stages of night blindness and Bitot's spots, to potentially blinding stages of corneal xerosis, ulceration and necrosis (keratomalacia),¹⁷ as listed in Table 1. The stages of xerophthalmia are regarded both as disorders and clinical indicators of VAD, and thus can be used to estimate an important aspect of morbidity and blinding disability as well as the prevalence of deficiency.

Subclinical Indicators of Vitamin A Deficiency

Measuring serum retinol concentrations in a population constitutes the second major approach to assessing vitamin A status in a population, with values below a cut-off of 0.70 µmol/L representing VAD,¹⁷ and below 0.35 µmol/L representing severe VAD. Although there is not yet international consensus, a serum retinol concentration below a cut-off of 1.05 µmol/L has been proposed to reflect low vitamin A status among pregnant and lactating women.¹⁷

TOXICITY OF VITAMIN A

Since vitamin A is a fat-soluble vitamin and is mainly stored in liver, routine consumption of large amounts of vitamin A results in toxic symptoms, including liver damage, bone abnormalities and joint pain, alopecia, headaches, vomiting, and skin desquamation. Hypervitaminosis A appears to be due to abnormal transport and

distribution of vitamin A and retinoids.¹⁶ Very high single doses can also cause transient acute toxic symptoms that may include bulging fontanelles in infants; headaches in older children and adults; and vomiting, diarrhea, loss of appetite, and irritability in all age groups.

VITAMIN A PROGRAMME IN INDIA—WHY THE CONTROVERSY?

The Universal Vitamin A Supplementation Programme in India

Since 1970, vitamin A supplementation programme has been operational in India. In 1970, it was initially started as the National Prophylaxis Programme against Nutritional Blindness as an urgent remedial measure to eliminate the unacceptably high magnitude of xerophthalmic blindness. But now it has been going on for the last four decades and its continuation has become a subject of national debate.

The controversy is not confined to the campaign-type approach to vitamin A distribution.¹⁸ Also in question is the very existence of vitamin A deficiency (VAD) as a public health problem in India and the need for supplementation.¹⁹

Recent Trend in Clinical Vitamin A Deficiency

In under-5 children, clinical vitamin A deficiency including severe xerophthalmia was a major public health problem in the early 1960's. However, in the past 4 decades keratomalacia has almost disappeared and there is a sharp decline in the prevalence of Bitot's spots.²⁰ This decline is due to better food availability, immunization coverage, access to healthcare facilities and management of childhood diseases. The available evidence indicates that this decline cannot be attributed to the UVAS programme. There is no obvious justification for continuing the UVAS programme to eliminate nutritional blindness.^{20,21} The advocacy of continuing this programme is now targeted towards the subclinical deficiency and the child survival benefits. Subclinical or biochemical vitamin A deficiency is overestimated in our setting because the serum retinol cut-offs are based on western population norms, where the main diet is non-vegetarian.

Child Survival Benefit

A systematic review of Indian trials concluded that for the prevention of mortality and morbidity, the findings of 'vitamin A trials are not consistent, and there is no evidence as yet in favor or against substantive benefit of universal vitamin A supplementation to children in India.'²²

Potential Harms Ignored

Potentially important and serious safety concerns have been ignored while framing policy regarding intensification of UVAS.

Table 1: Classification of xerophthalmia

XN	Night blindness
X1A	Conjunctival xerosis
X1B	Bitot's spot
X2	Corneal xerosis
X3A	Corneal ulceration/keratomalacia (< 1/3 corneal surface)
X3B	Corneal ulceration/keratomalacia (≥ 1/3 corneal surface)
XS	Corneal scar
XF	Xerophthalmic fundus

What Went Wrong with Vitamin A Campaign in Assam?

The reported deaths of over a dozen children and the illnesses of a large number following vitamin A administration during a mass campaign in 2001 in the north-eastern state of Assam had caused considerable anxiety and concern among health professionals.^{18,19,21} The campaign was stopped immediately and the Government set-up an inquiry which showed nothing wrong with the vitamin supplied. Since the rate of national immunization coverage is very low, some states including Assam had adopted the vitamin A campaign approach, with UNICEF support, to increase coverage.²¹ During third round, UNICEF replaced the traditional 2 ml spoons with 5 ml cups for administering vitamin A. It was possible that the newer method and inadequate training of health workers might have led to overdosing in some cases.

The Assam episode started with the death, after consuming vitamin A, of a two-year-old child from the Tea-garden community. This triggered panic among the parents. Thousands of people rushed with their children to the nearest health center, some of them complaining of fever, vomiting and diarrhea. Normally, these symptoms do not attract mass attention, but the media has sensationalized the event in Assam leading to a wave of mass concern. All deaths and illnesses that occurred in children during the following week were attributed to vitamin A. There is no evidence that vitamin A causes death, even if a child had received twice the recommended amount (400,000 IU). This is the dose recommended by the WHO for treatment of xerophthalmia. The vitamin A program has been in operation for the past several years in India and in sixty other countries. So far, not a single case of death attributable to vitamin A dosing was reported. The lethal dose of vitamin A is not known, but a review of the case reports of children getting 300,000 to 900,000 IU do not suggest severe toxic effects that could be fatal. It is not surprising that the investigation conducted by the State Department of Health and UNICEF revealed that, in most of the cases, deaths were due to causes unrelated to vitamin A.²¹

The Way Forward

The current evidence suggests that UVAS cannot be justified as a public health intervention for prevention of xerophthalmic blindness or childhood mortality in India. There is an urgent need of a national evidence-based process to examine an appropriate shift in the vitamin A supplementation policy.

Trace Elements in Pediatric Nutrition

Nita Radhakrishnan, GS Toteja

Although minerals constitute <5 percent of the daily dietary intake, they have a vital role in homeostasis. Trace elements are those minerals that are required in amounts of 1 to 100 mg daily in an adult and they constitute less than 0.01 percent of the body weight. The trace elements that are essential for human body are iron, zinc, copper, manganese, fluoride and selenium. Although iodine is required in amounts less than 1 mg daily, it also is a vital nutrient for human nutrition. Recommended intakes for trace elements are expressed as recommended dietary allowances (RDA) or adequate intake (AI). When limited data exists to assess the population needs of a trace element, the recommended intake is expressed as AI. The upper limit (UL) is the quantity of the nutrient considered to cause no adverse effects in healthy individuals.

CHROMIUM

Deficiency is noticed in patients who are hospitalized with increased catabolism (patients with burns, short bowel syndrome, trauma) and severe malnutrition. Low levels of chromium have been associated with impaired glucose tolerance and lipid profile. In diabetic patients on total parenteral nutrition, chromium deficiency has been associated with increased insulin requirement. Dietary sources of chromium include whole grains, fruits and vegetables.

COPPER

Although found in all organs and tissues of the human body, copper was recognized to be vital to human nutrition only recently. Around 60 percent of the dietary copper comes from vegetable products especially grains and pulses. Highest content of copper is found in liver. Copper plays a vital role in the functioning of many enzymes in homeostasis viz Zinc Copper superoxide dismutase, Dopamine mono-oxygenase, lysyl oxidase, ceruloplasmin, cytochrome C

oxidase, Factor V, tyrosinase, etc. Inherited diseases caused by inborn errors of copper metabolism include Wilson's disease and Menkes disease. Wilson's disease is characterized by signs and symptoms of copper toxicity whereas Menkes disease is a disorder of copper intake from the intestine, characterized by features of copper deficiency. Acquired causes of copper deficiency includes patients with malnutrition, following extensive gastric surgeries, formula-fed babies who have not received adequate supplementation, malabsorptive diseases, and patients on zinc supplementation also as zinc also retards copper absorption.

The recommended dietary intake of copper is 340 mcg daily for young children and 900 mcg for adults.

Deficiency

Deficiency of copper manifests with reduced skin pigmentation, muscle weakness, abnormal depigmented hair, neurological abnormalities like cognitive defects, ataxia, etc. anemia, hepatosplenomegaly and osteoporosis. Anemia is microcytic hypochromic and mimics iron deficiency. Treatment with iron supplements alone can worsen copper deficiency and iron further decreases copper absorption. Neutropenia and thrombocytopenia also may be noticed.

Menkes disease also known as Menkes kinky hair disease is an inherited X linked genetic disorder that occurs due to a mutation in the transport protein mediating copper absorption from the intestine. This results in severe copper deficiency with neurological deterioration. Hypopigmentation of skin and hair and bony abnormalities are the main clinical features.

FLUORIDE

Although fluoride is very common in the earth's crust, its concentration in water is very variable. Fluoride is important in preventing dental caries. Important sources of fluoride in

diet include seafood with edible shells and bones and dietary supplements. The adequate intake for fluoride is 0.7 mg daily for young children, and 3 to 4 mg daily in adults.

Deficiency has been found to increase the incidence of dental caries. Toxicity leads to pain abdomen, nausea and vomiting. Chronic toxicity leads to dental and skeletal fluorosis. Fractures are seen along with calcification of ligaments and tendons, leading to reduced joint mobility.

IODINE

Iodine is important for synthesis of thyroid hormones. It is predominantly found in the thyroid gland where it is bound to tyrosine as mono iodo and di-iodo tyrosine and thyroxine. Iodine deficiency leads hyperplasia of the gland and formation of goiter. Thyroid hormones have many physiological roles including regulation of basal metabolic rate. The recommended dietary intake of iron is 90 mcg for young children, 120 mcg for older children and 150 mcg in adolescents and adults. During pregnancy and lactation, the requirement increases to 220 to 290 mcg daily.

Deficiency of iodine is still a major public health problem in many countries. Iodine content of salt and water is very variable. Dietary sources include seafood and vegetables. Iodine fortified salt is the major source of iodine in many countries.

Deficiency leads to hypothyroidism, goiter, mental retardation and growth retardation in children. Maternal iodine deficiency leads to severe irreversible mental retardation in the fetus with deafness (cretinism).

IRON

Iron is the most widely accepted among all the known trace elements. Iron deficiency is a major public health issue worldwide. Among 1 to 1.5 billion of the world population is deficient in iron. Iron deficiency account for 20 to 30 percent of the infant and maternal mortality.

Sources: Iron is absorbed from the gut in 2 forms. Heme iron that is seen in meat and fish is absorbed directly unaffected by the underlying iron status. Nonheme iron is found in vegetables and fruits and iron fortified food products. Its absorption is dependant on transport proteins and it increases when the iron stores are low. Iron absorption is increased by vitamin C and reduced by calcium, phytic acid and tannins. Once absorbed, iron is bound to transferring which is a specific transport protein. During normal homeostasis, nontransferrin bound iron is very low and is taken up readily by the liver. Iron losses from the body are very low and occur in feces from desquamated cells and menstrual blood loss.

Inside the body, 75 percent of iron is in the form of heme proteins. These include hemoglobin, myoglobin, cytochrome C, cytochrome *p 450* and peroxidases. Twenty to thirty percent is in the form of storage proteins like

ferritin and hemosiderin. <1 percent is present in the form of iron metalloenzymes and are important in tyrosine, dopamine and nor adrenaline synthesis.

Deficiency or iron leads to the classical microcytic hypochromic anemia. Other features include tiredness, reduced work capacity and exercise tolerance and are not necessarily related to anemia. In children, iron deficiency also can lead to developmental delay, which may be irreversible, even when anemia is corrected. Maternal iron deficiency leads to premature birth and low birth weight.

Iron overload is seen in hereditary hemochromatosis. This is autosomal recessive and is characterized by iron overload, cardiomyopathy, cirrhosis of liver and diabetes. Iron overload is more commonly seen in diseases requiring repeated blood transfusions like thalassemias, bone marrow failure and malignancies.

MANGANESE

The role of manganese is still unclear in human health. Good sources of manganese are meat, fish, poultry, dried fruit and nuts. Inside the human body, manganese is found in bones, mitochondria (liver, kidney and pancreas) and melanin. The enzymes that require manganese for its metabolism include superoxide dismutase, arginase, glutamate synthetase and pyruvate carboxylase. The tolerable upper limit for manganese is 2 mg in toddlers and up to 11 mg in adults.

In animal models, deficiency leads to poor growth, reduced fertility, ataxia and skeletal deformities. In humans, deficiency has been noted in patients with severely restricted diet.

Toxicity has been observed on exposure to manganese containing dust as in welding and steel factories, as well as in individuals drinking well water with high content of manganese. Parenteral nutrition solutions contain manganese and has raised concerns about toxicity especially in neonates and children in the presence of cholestasis that decreases manganese excretion. Neurotoxicity due to extrapyramidal involvement manifesting as dyscoordination, loss of balance and confusion, hepatic dysfunction and headache has been reported.

SELENIUM

Selenium is a trace mineral with several vital biological functions. The dietary range is narrow and hence, it is potentially toxic. Selenium is seen in two selenium containing amino acids—selenocysteine and selenomethionine. This is incorporated in proteins like glutathione peroxidase and iodo thyronine deiodinase that are important for antioxidant function and thyroid hormone synthesis respectively. Seafood, kidney, liver and meat are good sources of selenium. The content in grains and nuts is variable and is dependant on the selenium content of soil.

Severe deficiency is associated with muscle dysfunction and impaired immune function. Keshan disease is an endemic cardiomyopathy that is linked to selenium deficiency. It has been reported in areas of China where diet is nearly absent in selenium. Chronic TPN users also have been reported to have selenium deficiency. In HIV infected patients, selenium deficiency has been associated with reduction in CD 4 cell counts. Cell mediated and NK cell mediated immunity also is impaired in selenium deficiency. The possibility that increased intakes of selenium might protect against the development of cancer in humans has generated great interest. Low serum selenium levels have been reported in pediatric and adult patients with cancers.

There have been studies linking selenium with prevention of atherosclerosis, but are not conclusive.

Toxicity of selenium occurs with increased dietary intake wither naturally or due to supplementation. Toxicity results in nausea, emesis, diarrhea, hair loss, mental changes and peripheral neuropathy. The recommended dietary intake is 20 mcg in children and 55 mcg daily in adults. Tolerable upper limit is 400 mcg/day.

ZINC

As a cofactor of more than three hundred enzymes, zinc is involved in a variety of general cellular functions, including signal transduction, transcription, and replication. The immune system as a highly proliferative organ is, therefore, strongly influenced by zinc. Dietary source of zinc are meat, nuts and lentils. Zinc absorption is regulated by a metallothionein that is more avid for copper. Hence, zinc supplementation is helpful in Wilson's disease as it competitively blocks copper absorption from the gut. Zinc is a vital component of >200 enzymes in the human body. The important enzymes requiring zinc include angiotensin converting enzyme, alkaline phosphatase, carbonic anhydrase, copper zinc superoxide dismutase and metallothionein.

Although the physiological plasma concentration of zinc is low (12–16 μM), it reflects only a minute component of the total body zinc. This part represents a very mobile and immunologically important pool. Bound to proteins, predominantly albumin, α_2 -macroglobulin and transferrin, zinc is transported to the cells but only free zinc ions seem to be biologically active. In chronic inflammatory conditions, a diminished serum zinc level is often found. This should not necessarily be interpreted as absolute zinc deficiency. More often it reflects a redistribution of serum zinc into the liver within the acute phase reaction, caused by increased production of proinflammatory cytokines, mainly interleukin (IL)-1 and IL-6, and subsequent induction of zinc-binding metallothionein in hepatocytes.

Zinc and Immunity

Decreasing zinc concentrations *in vivo* impair natural killer (NK) cell activity, phagocytosis of macrophages and

neutrophils and certain functions like chemotaxis and generation of the oxidative burst. *p58* killer cell inhibitory receptor (KIR) on NK cells requires zinc for recognition of MHC class I molecules, mainly HLA-C, on target cells.

Zinc deficiency interferes with the earliest steps of T cell maturation because it causes thymic atrophy. Zinc is an essential cofactor for thymulin, an important thymic hormone secreted by thymic epithelial cells and thymus changes are reversible by zinc substitution. Thymulin induces markers of differentiation in immature T cells in the thymus but also has effects in the periphery. It modulates cytokine secretion of peripheral blood mononuclear cells (PBMC) and, in conjunction with IL-2, induces proliferation of CD8 T cells. Zinc also influences maturation of T cells. It induces the expression of the high-affinity receptor for IL-2 and zinc deficiency is associated with decreased T cell proliferation after mitogen stimulation. Zinc regulates lymphocyte homeostasis not only by maintaining proliferation but also by inhibition of apoptosis.

At a molecular level, zinc-binding to specific membrane receptors could trigger a signal transduction cascade but, on the other hand, zinc could also exert its effects directly inside the cell.

Zinc has been shown to have immunomodulatory effects both directly, acting on the immune system and indirectly, acting on the respiratory, gastrointestinal and epithelial linings. Several studies have shown benefits of long-term zinc supplementation on the incidence, severity, and duration of diarrhea and on the incidence of respiratory infections. Prolonged zinc supplementation also improves cell-mediated immunity in severely malnourished children. Lymphocyte proliferation response and antigen specific IgG response are significantly higher after zinc supplementation compared with placebo. Zinc may also reduce the duration and severity of febrile neutropenia and associated complications.

Deficiency of zinc results in impaired growth velocity. Other features include delayed sexual maturation, hypogonadism, oligospermia, alopecia, altered taste, impaired wound healing and immune dysfunction. Skin changes include erythematous bullous or pustular lesions around body orifices, easy pluck ability of hair and changes in hair color. Deficiency has been observed in patients who are have chronic malnutrition, malabsorption, and following necrotizing enterocolitis in preterm infants.

Acrodermatitis enteropathica is an autosomal recessive condition with impaired zinc absorption.

Dietary requirement varies between 3 mg/days in children and 8 to 10 mg/day in adults.

Vitamin D and its Role in Health

Vasant Chinna Bhandar, Anupam Sachdeva, Satya P Yadav

Two forms of vitamin D exist: vitamin D₃ or cholecalciferol and vitamin D₂ or ergocalciferol. The former is produced in the skin under the influence of UVB radiation (UVR); the latter is produced by UVR in a variety of plant materials and yeast. The term “vitamin D” when used without further qualification or subscript refers to the total complement of both vitamin D₂ and vitamin D₃ or total complement of vitamin D₂ and vitamin D₃ metabolites. The active form of vitamin D (1,25 dihydroxy vitamin D [1,25(OH)₂D] is known as calcitriol. Vitamin D has been shown to have widespread and diverse activity in various body systems. The traditional role of vitamin D involves calcium absorption and skeletal health. Yet, we now know that many diverse cell types have the vitamin D metabolic machinery intact, and it has multiple functions.

The vitamin D system is complex, influencing expression of more than 200 genes, and is involved in many tissues—anything approaching even a partial understanding is many years away. Most tissues in the body have receptors for calcitriol. These receptors are named appropriately vitamin D receptors (VDRs), and tissues with VDR are potential target tissues.

In terms of evolution, two distinct functions of vitamin D exist. The more primitive function is that of a cytokine generated to protect the inside environment of the host (single cell organisms to man) from microbial invaders in the external environment.¹ The 1,25(OH)₂D cytokine is synthesized primarily by monocyte-macrophages and acts in an intracrine mode via interaction with the VDR to modulate the innate immune response to invading microbial agents.² When produced in sufficient quantities, 1,25(OH)₂D can escape the confines of the monocyte-macrophage to interact with and control the cytokine profiles of activated, VDR-expressing T- and B-lymphocytes in the local, inflammatory microenvironment (Table 1).¹

The more evolutionarily advanced function of vitamin D is that of a hormone. This function is reserved for species bearing an endoskeleton where the 1,25(OH)₂D hormone serves as a circulating regulator of both mineral and skeletal homeostasis in the host. The only recognized source of the hormone in man is the CYP27B1-hydroxylase; this enzyme is confined principally but not entirely to the proximal tubular epithelial cell of the kidney. 1,25(OH)₂D synthesis in the kidney is regulated by other hormones. It is stimulated primarily by PTH and inhibited by circulating fibroblast growth factor 23 (FGF23) made by osteocytes.³

VITAMIN D: AN OVERVIEW

Production

Vitamin D enters the human body through the production of vitamin D in the skin upon exposure to sunlight and through ingestion of either foods containing vitamin D₃, or vitamin D₂ (or dietary supplements of these

Table 1: Summary of distinctions between phylogenetically discrete functions of vitamin D one as a circulating hormone (left) and the other as a locally produced, locally active cytokine made by monocyte-macrophages (right)⁴

Hormone	Cytokine
Advanced function	Primitive function
Skeletal homeostasis	Host protection
Made by the kidneys	Made by macrophages
Acts at a distance	Acts locally
Regulated by hormones	Regulated locally
25D deficiency leads to increased 1,25D	25D deficiency leads to decreased 1,25D

Fig. 1: Metabolism of vitamin D₃ in the skin, liver and kidney⁵

substances). 7-dehydrocholesterol present in epidermal cells is converted to pre-vitamin D₃ upon exposure to UVR (wavelength, 290–315 nm). Following thermal rearrangement of triene system, vitamin D₃ (D₃) is released into the blood. The amount of D₃ made by the skin is determined by the exposure of the epidermal cells to UVR, which in turn depends on several geographical, physical, and cultural conditions. Some of the well-defined factors include proximity to the equator; altitude and degree of skin pigmentation. Cultural factors like type of clothing and use of sunscreen also affect vitamin D production.⁵

Metabolism (Fig. 1)

After entering the body through either endogenous production from the skin or through ingestion, D₃ is released into the circulation where the majority is quickly hydroxylated in the liver at the C25-position of the side chain. The product of this enzymatic modification, 25-hydroxyvitamin D₃ 25(OH)D₃; (25D₃) is the major circulating D₃ derivative. To be biologically active, vitamin D must first be converted to 25D₃. The enzyme that catalyzes the 25-hydroxylation of vitamin D is a cytochrome P-450-dependent enzyme. D₂ undergoes similar, if not identical metabolism after ingestion.⁵ In the discussion that follows the term “1,25D” is used to denote 1,25(OH)₂D derived from both D₂ or D₃.

The major circulating form of vitamin D, and the form that is currently used as a measure of an individual's

vitamin D status, is 25-hydroxyvitamin D (25D). The site of 25-hydroxylation of vitamin D is the liver where the enzyme 25-hydroxylase, a liver cytochrome P450 (CYP2R1) microsomal enzyme, acts as a specific hydroxylase. Recently, low levels of CYP2R1 have also been detected in the testis.

1 α ,25(OH)₂D (1,25D) is the primary hormonally active form of vitamin D. To be fully active, 25D must be further converted to 1,25D via CYP27B1, a mitochondrial P450 enzyme which acts as 1 α -hydroxylase. Although the proximal renal tubule is the major source of 1,25D production for the body, the enzyme is also found in a number of extrarenal sites such as immune cells, epithelia of many tissues, bone, and parathyroid glands,⁶ in which it functions to provide 1,25D for local consumption as an intracrine or paracrine factor.

Mechanism of Action (Fig. 2)

In an individual, changes in hormonal vitamin D metabolism and action occur quickly to maintain normocalcemia in the face of vitamin D insufficiency/deficiency and a reduction in the efficiency of intestinal calcium absorption. Decreased intestinal calcium absorption results in a small but real decrease in the serum calcium concentration as well. This decrease is detected by the calcium-sensing receptor in the plasma membrane of the parathyroid cell that activates a signal to release PTH from the gland and to increase PTH gene expression. Interaction of PTH

Fig. 2: Serial endocrine responses to a decrease in vitamin D directed intestinal calcium absorption in acquired vitamin D insufficiency/deficiency; the final step in the process is 1,25-D stimulation of genes controlling calcium absorption from the gut, mobilization of calcium from the skeleton and, finally, synthesis and release of FGF23, which acts to return previously enhanced PTH and CYP27B1-hydroxylase gene expression to normal. DBP, Vitamin D binding protein; RXR, retinoid X receptor

with the PTH/PTHrP receptor in the plasma membrane of the proximal tubular epithelial cell of the kidney signals an increase in CYP27B1 gene expression and conversion of available substrate 25D to 1,25D. 1,25D finds its way back into the serum and onto a serum vitamin D binding protein, whereby it gains access to control regions [vitamin D responsive elements (VDREs)] of VDR-regulated genes in the gut and bone to:

- Promote intestinal calcium and phosphate absorption.
- Liberate calcium and phosphate from the mineral phase of bone, respectively.

The mechanism of action of the active form of 1,25D is similar to that of other steroid hormones and is mediated by its binding to VDR. VDR is a member of the superfamily of nuclear hormone receptors including receptors for steroid and thyroid hormones and retinoic acid. VDR functions as a heterodimer generally with the retinoid X receptor for regulation of vitamin D target genes. These heterodimeric complexes interact with specific DNA sequences (VDREs), generally within the promoter of target genes, resulting in either activation or repression of transcription. The control of transcription requires the additional recruitment of co-regulators. These VDREs can be many thousand nucleotides away from the transcription start site, however.⁷⁻¹²

Regulation of 1,25D Synthesis in the Kidney

The three main influences on 1,25D production by the kidney are direct negative feedback by 1,25D itself,

parathyroid hormone (PTH) as a signal of calcium status and fibroblast growth factor 23 (FGF23) as a signal of phosphate homeostasis. Additionally 1,25D negatively regulates its own levels by inducing CYP24, like CYP27B1, a mitochondrial P450 that catabolizes both 1,25D and 25D.¹³

Once the deficit in the serum calcium concentration is corrected by the previously discussed means, the activated 1,25D:PTH axis is subsequently down-regulated by FGF23 released from bone.¹⁴

Feedback Regulation by 1,25D3

A universally observed negative feedback mechanism is the 1,25D status of the individual.¹⁵ This effect is a transcriptional one and is most likely mediated through the interaction of the hormone with its VDR. This down-regulates expression of the gene for CYP27B1 through a negative response element (nVDRE) in or near the promoter region of the gene.

Regulation of 1,25D Synthesis by Calcium/PTH

With deficiency of vitamin D there is a significant decrease in the intestinal calcium absorption. This leads to an increased secretion of parathyroid hormone (PTH). PTH in turn enhances the tubular reabsorption of calcium and stimulates the kidneys to produce 1,25D. It also activates osteoblasts, which stimulate the transformation of pre-osteoclasts into mature osteoclasts.^{8,16-19}

The activity of 1α -hydroxylase is inversely proportional to the dietary and serum calcium status. This regulation is mediated by PTH, the effect is exerted directly on the kidney cell, and it involves the second messengers generated by protein kinases A and C.²⁰ Regulation of the ability of the kidney to produce 1,25D by PTH is specific to the proximal cells of the kidney²¹ and is exerted at both the transcriptional and post-transcriptional levels. The promoter region of the CYP27B1 gene contains a region that renders its transcription sensitive to stimulation by PTH.^{22,23} Recently a role for DNA methylation and demethylation in the regulation of CYP27B1 expression by PTH has been reported with demethylation and transcriptional activity resulting from PTH stimulation.²⁴

Regulation of 1,25D by Phosphate/FGF23 (Fig. 3)

Hypophosphatemic disorders are associated with renal phosphate excretion, defective skeletal mineralization, osteomalacia in adults and rickets in children and inappropriately (for the given serum phosphate levels) low serum 1,25D levels. In addition to the role of FGF23 as the hypophosphatemic agent it also seems to mediate the regulatory effect of serum phosphate levels on vitamin D metabolism, in particular the lowering of 1,25D levels in the blood.²⁵ The underlying mechanism by which the synthesis and secretion of FGF23 synthesis in the bone cells is stimulated by elevated phosphate levels has not been elucidated, but it is clear that FGF23 is integral to

maintenance of phosphate homeostasis, one aspect of which is the modulation of vitamin D metabolism.

As previously mentioned, PTH, secreted in response to low serum calcium levels, stimulates the transcription (and possibly post-transcriptional activation) of CYP27B1 and 1,25D inhibits it. Since 1,25D also stimulates the movement of phosphate into the blood from the intestine and bone, it is not surprising that an inverse relationship between the synthesis and circulating concentrations of 1,25D and the serum phosphate levels has been known for decades. Recent studies have shown that the basis of this relationship lies in the inhibition of the transcription of CYP27B1 in the kidney by FGF23, which is secreted by bone osteocytes in response to elevated serum phosphate concentrations. Thus, in the kidney FGF23 causes, at the same time, increased phosphate excretion in the urine, through reduction in the number of sodium-phosphate co-transporters in the brush border membranes^{26,27} and decreased 1,25D synthesis by the proximal renal tubules.²⁸

Extrarenal 1,25D Production

Although the kidney is the major endocrine organ that produces 1,25D in response to other calcium- and phosphate-regulating hormones, the presence of CYP27B1 and the ability to convert 25D to 1,25D in fact resides in many other tissues (major sites previously mentioned). In general extrarenal 1α -hydroxylase activity is not regulated by

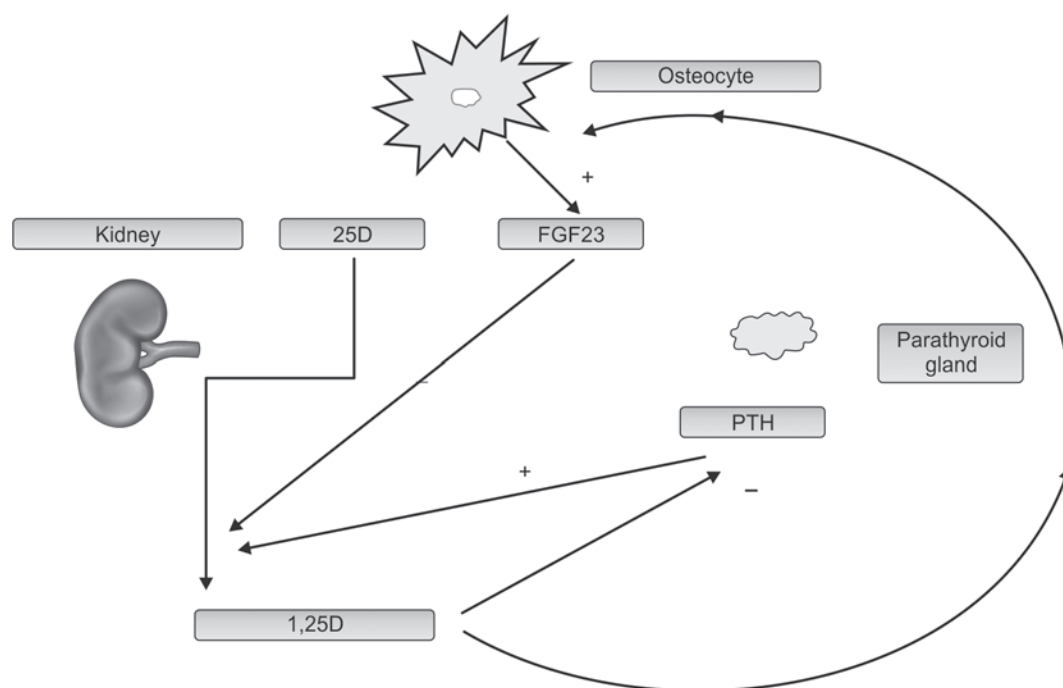

Fig. 3: Regulation of 1,25D production in the kidney. PTH stimulates and FGF23 inhibits 1,25D production in the kidney. In turn 1,25D inhibits PTH production and secretion from the parathyroid glands and stimulates FGF23 production from bone

the classical calcium and phosphate-regulating hormones, but the enzyme's activity may be subject to changes specific to the cell's environment or function.

Control of 1,25D production (and levels) by non-renal tissues differs. When macrophages are activated via specific toll-like receptors (TLRs), CYP27B1 is induced. In these cells 1,25D production appears to be governed primarily by the availability of substrate.²⁹ The keratinocyte also contains CYP27B1, which like the macrophage enzyme can be induced by activation of specific TLRs.³⁰ Both TNF- α and interferon (IFN)- γ stimulate 1,25D production by keratinocytes, suggesting that the keratinocyte like the macrophage uses 1,25D for important host defence mechanisms.^{31,32}

Inactivation of 1,25D in its Target Tissues

CYP24 is one of the most dramatically activated genes in target tissues of 1,25D with increases of mRNA levels from barely detectable to several hundred or a few thousand fold above basal levels. Clearly the induction of this CYP24, which can carry out the catabolism of 1,25D to inactive product(s) is an important element of negative feedback to curtail the hormone's action in its target cells.

Renal Production of 24,25D

The physiological significance of 24R,25D has long been the subject of debate. The kidney produces circulating levels of 24,25D and it is known that renal 24R hydroxylase activity is inversely related to 1 α -hydroxylase activity. This is largely due to the opposing effects of 1,25D on the expression 24R-hydroxylase activity (stimulation) and 1 α -hydroxylase expression.

Sources and Daily Requirements in the Pediatric Population (Table 2)

A potential source of vitamin D is synthesis in the skin from the ultraviolet-B light fraction of sunlight. However, the amount of vitamin D synthesized in the skin varies widely due to factors previously discussed. This makes it very difficult to determine the adequacy of sunshine exposure for any given infant or child.

The usual diet of infants contains only small amounts of vitamin D. Breast milk content is low, and bovine milk content is even lower. Human milk typically contains a vitamin D concentration of 25 IU/L or less.³³⁻³⁵ Thus, the recommended adequate intake of vitamin D cannot be met with human milk as the sole source of vitamin D for the breastfeeding infant. Cereals, vegetables, and fruits contain only negligible amounts. Vitamin D sources are limited in the diet and mainly include oily fish, mushrooms, and some fortified milks and foods.

The previous AI was 200 IU/day for all infants and children.³⁶ The authors of two recent statements (a joint

Table 2: Vitamin D intake recommendations⁴⁴

Age	Vitamin D, recommended intake ^a (IU/d)
0-6 months	400
6-12 months	400
1-3 years	600
4-8 years	600
9-18 years	600

a: Recommended intake values are the RDA values for children aged 1 year and older. AI values for infants younger than 1 year.

report from the American Academy of Pediatrics Committee on Nutrition and Section on Breastfeeding³⁷ and a separate statement from the Pediatric Endocrine Society [PES]³⁸ recommended a vitamin D intake of 400 IU/day for all children; in addition, the PES statement indicated a usual target for serum 25D (25[OH]) of ≥ 50 nmol/L (20 ng/ml).³⁸ Vitamin D deficiency is defined by most experts as a 25D level of less than 20 ng/ml (50 nmol/L).³⁹⁻⁴² A level of 25D of 21 to 29 ng/ml (52-72 nmol/L) can be considered to indicate a relative insufficiency of vitamin D, and a level of 30 ng/ml or greater can be considered to indicate sufficient vitamin D.⁴³

Role of Vitamin D in Health

Traditionally vitamin D has been known to be involved in calcium absorption and skeletal health. Vitamin D is essential for normal mineralization of bone or osteoid tissue.

Osteoblasts initiate new bone formation and are responsible for matrix deposition and subsequent mineralization. They secrete collagen and changes in polysaccharides, phospholipids, alkaline phosphatase, and pyrophosphatase follow until mineralization occurs. However, normal mineralization occurs only in the presence of adequate calcium and phosphorus. Osteoclasts on the other hand are responsible for resorption of bone through enzymes secreted on the bone surface, which dissolve and remove both matrix and mineral. Osteocytes covered by bone both resorb and redeposit bone. Many incompletely delineated factors affect bone growth through poorly defined pathways, but phosphorus, calcium, fluoride, and growth hormone are known to be involved.

Vitamin D deficiency leads to low serum calcium levels which in turn stimulates calcium release from the bones to maintain normocalcemia. However, this is at the cost of decreased bone mineralization. In the absence of vitamin D, only 10 to 15 percent of dietary calcium and about 60 percent of phosphorus is absorbed.^{8,17,18} The interaction of 1,25D with the vitamin D receptor increases the efficiency of intestinal calcium absorption to 30 to 40 percent and phosphorus absorption to approximately 80 percent.⁴⁵ Deficiencies of calcium and vitamin D in utero and

in childhood may prevent the maximum deposition of calcium in the skeleton.³⁶ As vitamin D deficiency progresses, the parathyroid glands are maximally stimulated, causing secondary hyperparathyroidism.^{39,41-43} In children, the deficiency of vitamin D leads to rickets (discussed extensively in a separate chapter).

Vitamin D deficiency causes muscle weakness. Skeletal muscles have a vitamin D receptor and may require vitamin D for maximum function.^{16,39,40,46}

Nonclassic Roles of Vitamin D

Over the last few years it has been found the VDRs are present in most of the body tissues in humans. Also, many of these tissues contain CYP27B1 which is essential for the synthesis of 1,25D. Hence, in the past few years, there has been growing appreciation for the many roles of vitamin D and its active metabolites in a large number of tissues. An exciting concept regarding the role of vitamin D in a large number of physiologic functions beyond that of the classic actions involved with bone mineral metabolism is rapidly emerging.

Based on recent research in this area, the nonclassic actions of vitamin D can be categorized into three general effects:

1. Regulation of hormone secretion.
2. Regulation of immune function.
3. Regulation of cellular proliferation and differentiation.

REGULATION OF HORMONE SECRETION AND METABOLISM

Vitamin D has a relatively well-known role in regulation of hormone secretion to control bone mineral density. 1,25D inhibits the secretion of PTH and prevents the proliferation of the parathyroid gland.^{47,48} This action is mediated through a negative VDRE on the parathyroid gene. 1,25D also upregulates the calcium-sensing receptor,⁴⁹ thus sensitizing the parathyroid gland to calcium inhibition and providing an additional means by which 1,25D regulates PTH production and secretion. PTH stimulates 1,25D production in the kidney, hence this inhibition of PTH production and secretion provides an important feedback loop. These actions of 1,25D are exploited clinically through the use of 1,25D and analogs to control secondary hyperparathyroidism in renal failure. Furthermore, the ability of the parathyroid gland to make its own 1,25D provides an explanation for the reciprocal relationship between 25D and PTH levels, but not between 1,25D and PTH levels, in the blood of subjects with vitamin D insufficiency.⁵⁰

Apart from this, its role in insulin secretion is a recently identified area of nonclassic action that appears to have significant therapeutic importance. 1,25D stimulates insulin secretion and significant case control and observational studies have suggested that vitamin D deficiency may

contribute to increased risk for type 2 diabetes mellitus. The mechanisms by which this effect is mediated have still not been fully elucidated, however VDR and calbindin-D28k are found in pancreatic β -cells,^{51,52} and studies using calbindin-D28k null mice have suggested that calbindin-D28k, by regulating intracellular calcium, can modulate depolarization-stimulated insulin release.⁵³ Furthermore, calbindin-D28k, by buffering calcium, can protect against cytokine mediated destruction of β -cells.^{54,55}

FGF23 is primarily produced by osteoblasts and osteocytes in the bone. 1,25D stimulates this process by ill-defined pathways.⁵⁶ FGF23 in turn inhibits renal synthesis of 1,25D, thus forming a negative feedback loop which ensures control over the levels of these important hormones. Mutations in the phosphate-regulating gene on the X chromosome (PHEX) or FGF23 itself (which prevent its proteolysis) or conditions such as McCune-Albright disease and tumor-induced osteomalacia in which FGF23 is over-expressed in the involved tissue lead to hypophosphatemia and inappropriately low 1,25D accompanied by osteomalacia.

There is growing evidence of association of low 25D levels with increase in cardiovascular mortality in the form of coronary artery disease, heart failure and peripheral vascular disease.⁵⁷ In fact, review of recent vitamin D deficiency epidemiological data has revealed a striking inverse correlation of the 25D levels not only to cardiovascular disease but also to essentially all elements of the human metabolic syndrome, namely (1) hypertension, (2) obesity and (3) insulin resistance and glucose intolerance.

Vitamin D-Fat-Bone Axis: An intriguing new hypothesis postulates that there may be causal association between increasing obesity, its attendant cardiovascular risks and vitamin D deficiency/insufficiency. Low 25D levels observed in association with obesity may be due in part to: (1) the increased volume of distribution to fat of lipid soluble vitamin D as it leaves the general circulation after being synthesized in the skin or obtained through the diet; and (2) preferential retention of vitamin D in those fat stores. Also, studies in mice indicate that vitamin D deficiency may promote increase in body weight by itself. It is hypothesized that this increase in body fat mass acts in a “feed-forward” fashion to further increase the volume of distribution for vitamin D, deepen the state of vitamin D deficiency, and amplify the consequences of secondary hyperparathyroidism on the skeleton and body fat. There are some data now to suggest that there exists a leptin-mediated “negative feedback” loop to interrupt this cycle of fat accumulation.⁵⁸

REGULATION OF IMMUNE FUNCTION

Three important discoveries about two decades ago heralded the identification of the potential role of vitamin D and 1,25D in the modulation of immune response. These were:

- The presence of VDRs in activated human inflammatory cells.⁵⁹
- The ability of 1,25D to inhibit T cell proliferation.⁶⁰
- The ability of disease activated macrophages to produce 1,25D (i.e. express CYP27B1)⁶¹

Vitamin D and CYP27B1 both play notable roles in innate and adaptive immunity. In this regard the description of cathelicidin, an antimicrobial peptide that enhances killing of the mycobacterium tuberculosis is notable.² The monocyte activated by mycobacterial lipopolysaccharide induces CYP27B1 which in turn produces 1,25D. This 1,25D induces the production of cathelicidin. Other recent studies have shown that 1,25D-directed production of cathelicidin is not restricted to monocyte-macrophages. Indeed, this appears to involve an antimicrobial mechanism also employed by epithelial cells from a variety of tissue “barrier” sites, like the gut,⁶² lung,⁶³ placenta,⁶⁴ and skin.⁶⁵⁻⁶⁸

Also, it has been observed in several studies that vitamin D deficiency and/or living at higher altitudes (i.e. lesser sunlight) is associated with several autoimmune diseases like type 1 diabetes mellitus, multiple sclerosis, and Crohn's disease.⁶⁹ In a large Finnish study, providing infants with 2000 IU vitamin D for their first year of life reduced the incidence of type 1 diabetes mellitus by 80%.⁷⁰ Other studies have linked vitamin D deficiency to increased risk of multiple sclerosis, asthma, and other immunologic diseases.^{71,72}

Role of Vitamin D in Regulation of Adaptive and Innate Immunity

Vitamin D has an inhibitory action on the adaptive immune system. Adaptive immunity is constituted by the ability of the B- and T-cells to secrete immunoglobulins and cytokines respectively in response to specific antigenic stimulation. In particular, 1,25D suppresses proliferation and immunoglobulin production and retards the differentiation of B-cell precursors into plasma cells.⁷³ It also inhibits T-cell proliferation, especially T helper (Th-1) cells capable of producing IFN- γ and IL-2 and activating macrophages.⁷⁴ In contrast IL-4, IL-5, and IL-10 production can be increased, shifting the balance to a Th-2 cell phenotype. CD4/CD25 regulatory T cells (Treg) are also increased by 1,25D.^{75,76} At least in part, these actions on T cell proliferation and differentiation stem from actions of 1,25D on dendritic cells to reduce their antigen presenting capability.

As previously mentioned 1,25D has a beneficial role in many autoimmune conditions due to its propensity to suppress adaptive immunity.

Activation of toll like receptors (TLRs) in polymorphonuclear cells, monocytes, macrophages and also lining epithelium in various tissues plays a central role in innate immunity. This leads to the induction of antimicrobial

peptides and reactive oxygen species, which kill the organism. Among those antimicrobial peptides is cathelicidin, an antimicrobial peptide that is induced by 1,25D in both myeloid and epithelial cells.^{77,78} Stimulation of TLRs by appropriate inflammatory stimuli leads to increased expression of CYP27B1, thus eliciting expression of cathelicidin in the presence of adequate 25D.

Regulation of Proliferation and Differentiation

Vitamin D has a unique relation with the keratinocyte in the epidermis. It is not only synthesized in this cell, but it can also be converted to its active form here and finally the keratinocyte is capable of responding to this 1,25D. It enables this cell to mount an innate immune response, promotes its differentiation and also inhibits its proliferation. Vitamin D is closely linked to the sequential differentiation and orderly progression of the keratinocyte from the basal layer of the epidermis to ultimately forming the enucleated corneocyte (permeability barrier of the skin).

Hair follicle cycling is the best example of a role for VDR independent of 1,25D. The mechanism by which VDR regulates hair follicle cycling remains unclear. Studies suggest an important role for the VDR in regulating the proliferation and differentiation of these cells during the process of hair follicle cycling.⁷⁹

Analogues of 1,25D, such as calcipotriol, as well as calcitriol itself have proved effective therapy for moderate forms of psoriasis.⁸⁰ This form of therapy likely works by inhibiting the inflammatory component via a direct action on the T-cells⁸¹ as well as by reducing keratinocyte proliferation and enhancing their differentiation.⁸²

Role in cancer: A variety of malignant cells express VDRs. The hypothesis proposed to explain the possible role of vitamin D in the prevention and treatment of cancer includes its anti-proliferative, pro-differentiating effects on most cell types. In particular 1,25D stimulates the expression of cell cycle inhibitors p21 and p27 and the expression of the cell adhesion molecule E-cadherin and inhibits the transcriptional activity of β -catenin.⁸³⁻⁸⁶ In keratinocytes, 1,25D has been shown to promote the repair of DNA damage induced by UVR,⁸⁷ reduce apoptosis and increase survival after UVR, and increase p53.⁸⁸ There is epidemiological evidence to support the role of adequate vitamin D in the prevention of cancers. However, some recent trials have provided inconclusive and often conflicting data regarding the ability of this vitamin to prevent cancer.^{89,90} Trials of 1,25D and its analogues for the treatment of cancer have been disappointing. Studies in prostate cancer^{91,92} have shown some possible role for vitamin D in therapy. But the results have not been uniform. Hypercalcemia and hypercalciuria have been noted as significant adverse effects following therapy with vitamin D in some studies. It is likely that role of vitamin D

in cancer therapy will be better realized only once a non-hypercalcemic and efficacious vitamin D analog is developed.

MISCELLANEOUS FUNCTIONS

Schizophrenia and mental illness: Maintenance of adequate vitamin D levels in utero and early life may be essential to satisfy the vitamin D receptor transcriptional activity in the brain, may be important for brain development as well as for maintenance of mental function later in life.⁹³

Wheezing illness: Normal levels of vitamin D have been shown to help maintain higher levels of forced expiratory volumes at one second on pulmonary function testing. Vitamin D deficiency during pregnancy has been associated with higher incidence of wheezing illnesses in their children.

Hypervitaminosis D

Both ergocalciferol and cholecalciferol can be used for the treatment and prevention of vitamin D deficiency.⁹⁴ Many people consume vitamin supplements on the assumption that vitamins are safe, and while there is a large margin of safety between adequate vitamin D levels and toxicity, this can result in toxicity. Patients should be advised to desist from self-prescription and use of vitamin supplements, especially for prolonged periods and to always consult their health care provider before initiating vitamin D supplementation at a daily dose greater than 1000-2000 IU. This will go a long way in ensuring that the intended dose is safe and that appropriate monitoring is performed if necessary.

Hypervitaminosis D has rarely been reported and usually occurs in the setting of gross excess of supplemental vitamin D₂ or D₃.⁹⁵⁻⁹⁷ Because any excess previtamin D₃ or vitamin D₃ is destroyed by sunlight, excessive exposure to sunlight does not cause vitamin D₃ intoxication. The main toxicities of hypervitaminosis D are hypercalcemia and hyperphosphatemia. Hypervitaminosis D is unlikely to occur until the 25D level, the main storage form of vitamin D, exceeds 150 ng/mL.⁹⁸ Patients may also experience nonspecific symptoms such as nausea, vomiting, anorexia, confusion, and weakness, typically secondary to the resulting hypercalcemia.⁹⁹ The upper limit of daily vitamin D intake required to cause toxicity is unknown; however, up to 10,000 IU daily has been considered safe in a healthy population.⁹⁸ Patients with chronic granulomatous disorders are more sensitive to serum 25D levels above 30 ng/mL because of macrophage production of 1,25D, which causes hypercalciuria and hypercalcemia.¹⁰⁰

Discontinuation of any supplements being used should be the first step in the management of hypervitaminosis. Decreasing calcium intake is also an essential measure. In more severe cases oral aluminium hydroxide is useful as

adjunctive therapy. Occasionally, chelation therapy may be indicated.

Malnutrition in Children

Raghvendra Singh, SK Mittal

Malnutrition is a state of deficiency or excess of energy, protein, and other nutrients, this chapter deals with under nutrition and specifically protein energy malnutrition (PEM). Under nutrition ranges from a lower than desired intake of one or more nutrients leading to a clinical spectrum from no symptoms or only vague symptoms to severe malnutrition. World Health Organization (WHO) defines malnutrition as “the cellular imbalance between the supply of nutrients and energy and the body’s demand for them to ensure growth, maintenance, and specific functions.” Some pediatric textbooks use the term severe childhood undernutrition (SCU) as an alternative to PEM as it is always accompanied by deficiencies of other nutrients. The terms primary malnutrition and secondary malnutrition refer, respectively, to malnutrition resulting from inadequate food intake and malnutrition resulting from increased nutrient needs, decreased nutrient absorption, and/ or increased nutrient losses.¹

FAILURE TO THRIVE (FTT) VS MALNUTRITION

Failure to thrive (FTT) as understood in the western texts, was not usually considered to be primarily due to dietary malnutrition and was divided into either Organic FTT, marked by an underlying medical condition or nonorganic or psychosocial FTT. However if applied generically, the term FTT only means failure to gain weight adequately which in the larger context (especially in developing country context) is mostly due to dietary malnutrition. As failure to thrive indicates impairment of growth velocity, it helps to detect growth faltering (malnutrition) at the earliest when absolute growth values may still be within the normal range.

However western texts now consider the term FTT (as used earlier) as an imprecise, archaic and obsolete term.² It is now recognized that in all cases of nonorganic FTT and few cases of organic FTT, the proximate cause of

growth failure is malnutrition whether primary or secondary. The modern diagnosis and treatment of FTT focus on the assessment and therapy for malnutrition and its complications.^{3,4} It is suggested that growth failure or growth faltering may be a better term in place of FTT.²

BURDEN OF MALNUTRITION

International

Among the four principal causes of mortality in young children worldwide, undernutrition has been ascribed to be the cause of death in 60 to 70 percent of children with diarrheal diseases, 52.3 percent of those with pneumonia, 44.8 percent of measles cases, and 57.3 percent of children with malaria.⁵ Malnutrition is a major public-health problem throughout the developing world and is an underlying factor in over 50 percent of the 10–11 million children under 5 years of age who die each year of preventable causes.^{6,7}

National

Almost half of children under five years of age (48 percent) are stunted and 43 percent are underweight. The proportion of children who are severely undernourished (more than three standard deviations below the median of the reference population) is also notable—24 percent according to height-for-age and 16 percent according to weight-for-age. Wasting is also quite a serious problem in India, affecting 20 percent of children under five years of age (Fig. 1). Very few children under five years of age are overweight.

Undernutrition is substantially higher in rural areas than in urban areas. Even in urban areas, 40 percent of children are stunted and 33 percent are underweight. Children who are judged by their mothers to have been small or very small at the time of birth are more likely to be undernourished than those who were average size or larger. Thus

Fig. 1: Proportion of malnourished children 0-59 months NFHS-3, India

Fig. 2: Trends in nutritional status in India

low birth weight is a major contributing factor to deficient growth in under 5 children. Undernutrition has a strong negative relationship with the maternal education.⁸

The nutritional status of children is strongly related to maternal nutritional status. Undernutrition is much more common for children of mothers whose body mass index is below 18.5 than for children whose mothers are not underweight. In NFHS-3 compared to NFHS-2, the prevalence of children who were underweight decreased slightly more in urban areas than in rural areas, but there was very little improvement in the percentage of children who were severely underweight, even in urban areas (Fig. 2).⁸

ANTHROPOMETRY

Anthropometric parameters can assess growth cross-sectionally or longitudinally. If children are measured once, their growth status for age can be assessed by comparing this measurement with the appropriate reference curve.

If they are measured more than once, and plotted on an appropriate growth curve, growth velocity data is obtained which can be even more useful. Particular care should be taken to use appropriate equipment and techniques for measurement of stature/length and weight.

Weight

Infant scales, beam balances and readout scales are available. Preferably the nude weight should be taken (to the least count of the available scale after correcting the zero error/calibration) or else the estimated weight of the clothing should be subtracted. The newborn weight should be taken close to the nearest gram. As weight is the earliest anthropometric parameter to be affected by undernutrition, it is the most important index of early and current malnutrition.

Length and Height

It is the most useful indicator of long term growth status. Recumbent length is measured in children less than 2 years of age and stature/standing height is measured in children more than two years of age. It is most important that correct methodology is followed when either of the parameters are being recorded. When possible, the parents' stature should be taken to determine the influence of genetics on growth. Length or height is affected in long standing malnutrition, therefore stunting is usually a reflection of long standing undernutrition.

Head Circumference

It must be measured with a narrow and a nonstretchable tape. It is a useful parameter until 3 years of age when the head growth slows down.

Mid Upper Arm Circumference (MUAC)

The MUAC is an indicator of muscle growth in all ages. This is also a labile (early affected) parameter of nutrition.

GROWTH STANDARDS

In 2006, the WHO released new multicentric growth reference standards (MGRS) for assessing the growth and development of children from birth to 5 years of age. These new standards are based on breastfed infants and appropriately fed children of different ethnic origins raised in optimal conditions and measured in a standardized way. The WHO charts are based for the first time on a prescriptive, prospective, international sample of infants selected to represent optimum growth. The MGRS was a population-based study conducted between 1997 and 2003 in Brazil, Ghana, India, Norway, Oman, and the United States. The MGRS combined a longitudinal follow-up from birth to 24 month with a cross-sectional component of children aged between 18 and 71 month. In the longitudinal component, mothers and newborns were enrolled at birth and visited at home a total of 21 times at week 1, 2, 4 and 6; monthly from 2 to 12 months; and bimonthly in the 2nd year. In the cross sectional component the children were exclusively breast fed for a minimum of 3 months and appropriate complementary feeds introduced. The same cohort was used to produce standards of MUAC in relation to age. The new WHO growth standards confirm earlier observations that the effect of ethnic differences on the growth of infants and young children in populations is small compared with the effects of the environment. Studies have shown that there may be small ethnic differences among groups, just as there are genetic differences among individuals, but for practical purposes they are not considered large enough to invalidate the general use of the WHO growth standards population as a universal standard. These new standards have been endorsed by international bodies such as the United Nations Standing Committee on Nutrition, the International Union of Nutritional Sciences and International Pediatric Association and have been adopted in more than 90 countries. Even the CDC now recommends the use of WHO standards in US population up to 2 years of age (Table 1).

Growth Reference vs Growth Standard

The CDC and WHO growth charts differ in their overall conceptual approach to describing growth. The WHO charts are growth standards that describe how healthy children should grow under optimal environmental and health conditions whereas CDC growth charts are a growth reference, not a standard, and describe how certain children grew in a particular place and time. The numerous

concerns about the CDC charts include a lack of racial diversity in the infant sample, an infant sample composed of infants who were almost all formula fed, and the disjunction in length and stature measurements when transitioning from the charts for younger children to those for older children. Also there are concerns that the CDC charts are predisposing children to obesity by promoting excessive weight gain in infancy.

Age Independent Nutritional Anthropometry (Table 2)

Recording of individual parameters of growth and comparing them with reference standards for the age is used for assessing and grading the nutritional status. However in actual field conditions actual age of the child is often not available, then a comparison of a relatively labile parameter (weight/mid arm circumference, etc.) with a 'nonlabile' parameter like length/height or head circumference can be used to assess nutritional status. Various indices have been arrived at for use as tools in this 'Age Independent Nutritional Anthropometry' (Table 2). Kanawati index is one such which is obtained by dividing mid arm circumference by head circumference. More than 0.31 is normal.

Mid Upper Arm Circumference

Requires minimum equipment and is relatively stable between 1 and 5 years with a value between 16 and 17 cm. Any value below 13.5 cm is abnormal and suggestive of malnutrition. WHO recommends MUAC to be used in girls and boys 6 to 59 months of age, as an age independent criteria for assessing malnutrition. A value below 115 mm is an independent indicator for severe malnutrition. Shakir's Tape is a useful tool for peripheral health worker as it utilizes the MUAC in three visual zones-Red <12.5 cm, yellow between 12.5 and 13.5 cm (Borderline) and green >13.5 cm (Normal).

Bangle test: A bangle is passed above the elbow, whose internal diameter is 4 cm (circumference about 12.5 cm). If the bangle can be passed above the elbow it indicates that the child has severe malnutrition (Table 3).

Cole's classification: Cole's classification is another alternative classification based upon the use of BMI scores for the classification of malnutrition. It classifies low BMI scores for age as thinness in children and adolescents. Low BMI scores correlate well with low lean body mass and not just the opposite of fatness as in thin children BMI is a better predictor of lean mass than fat mass.¹⁰

IAP classification of malnutrition: IAP classification is a modified Jelliffe's classification based on weight for age values based on the 50th centiles of older Harvard standards. This classification is still used in the ICDS classification of malnutrition to be used by peripheral health worker (Anganwadi worker) (Table 4).

Table 1: Growth charts WHO vs CDS standards⁹

<i>Characteristic</i>	<i>CDC growth reference (2000)*</i>	<i>WHO growth standard (2006)⁺</i>
Data sources	National vital statistics (birth weights) Missouri and Wisconsin vital statistics (birth lengths) Pediatric Nutrition Surveillance System (lengths, 0.1 to <5 mos) NHANES I (1971–1974) (12–23 mos) NHANES II (1976–1980) (6–23 mos) NHANES III (1968–1994) (2–23 mos)	MGRS longitudinal component, with sites in the following locations: Pelotas, Brazil Accra, Ghana Delhi, India Oslo, Norway Muscat, Oman Davis, California
Type and frequency of data collection	Cross-sectional data on weight and length starting at age 2 mos, with mathematical models used to connect birth weights and lengths to survey data	Longitudinal data with measurements of weight and length at birth; 1, 2, 4, 6, and 8 wks; and 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 14, 16, 18, 20, 22, and 24 mos
Sample size	4,697 observations for 4,697 distinct children	18,973 observations for 882 distinct children
Exclusion criteria	Very low birth weight (<1,500 g [<3 lbs, 4 oz])	Low socioeconomic status Birth at altitude > 1,500 m Birth at <37 wks or ≥42 wks Multiple birth Perinatal morbidities Child health conditions known to affect growth Maternal smoking during pregnancy or lactation Breastfeeding for <12 mos Introduction of complementary foods before age 4 mos or after age 6 mos Weight-for-length measurements >3 standard deviations above or below study median for sex
Breastfeeding among infants in sample	Approximately 50% ever breastfed Approximately 33% breastfeeding at 3 mos	100% ever breastfed 100% predominantly breastfeeding at 4 mos 100% still breastfeeding at 12 mos Complementary foods introduced at mean age of 5.4 mos

Kanawati	MUAC divided by occipito frontal head circumference	Mild Moderate Severe	<0.31 <0.28 <0.25
Cole	Z scores of BMI for age	Grade 1 Grade 2 Grade 3	BMI for age z score < -1 BMI for age z score < -2 BMI for age z score < -3

Table 4: IAP classification of malnutrition (0-6 years)

Grade of Malnutrition	% Wt. for age of standard median *
Normal	>80
Grade I	71-80
Grade II	61-70
Grade III	51-60
Grade IV	<50

*50th percentile of Harvard Standard is taken as standard median

WELLCOME TRUST CLASSIFICATION OF MALNUTRITION

This system takes weight for age and presence or absence of edema for classifying malnutrition.

Weight for age	Edema	Type of malnutrition
>80%	Nil	Normal
>80%	+ve	no undernutrition (Look for cause of edema)
60–80%	–ve	Undernutrition
60–80%	+ve	Kwashiorkor
<60%	–ve	Marasmus
<60%	+ve	Marasmic Kwashiorkor

WHO CLASSIFICATION OF MALNUTRITION

As per WHO severe malnutrition is defined if the child has either edematous malnutrition or has body weight (for height) less than -3 SD (wasting). Moderate malnutrition is defined if the body weight is between -2 SD and -3 SD.

Similarly stunting is classified as severe if the height for age is <3 SD (less than 85% of expected) (Table 5).

ECOLOGICAL OF MALNUTRITION

A large number of socioeconomic factors are involved in causation of malnutrition in a child. Poverty, illiteracy, lack of health education, poor environmental sanitation (with increased diseases burden) are some of these factors. (Flow chart 1).

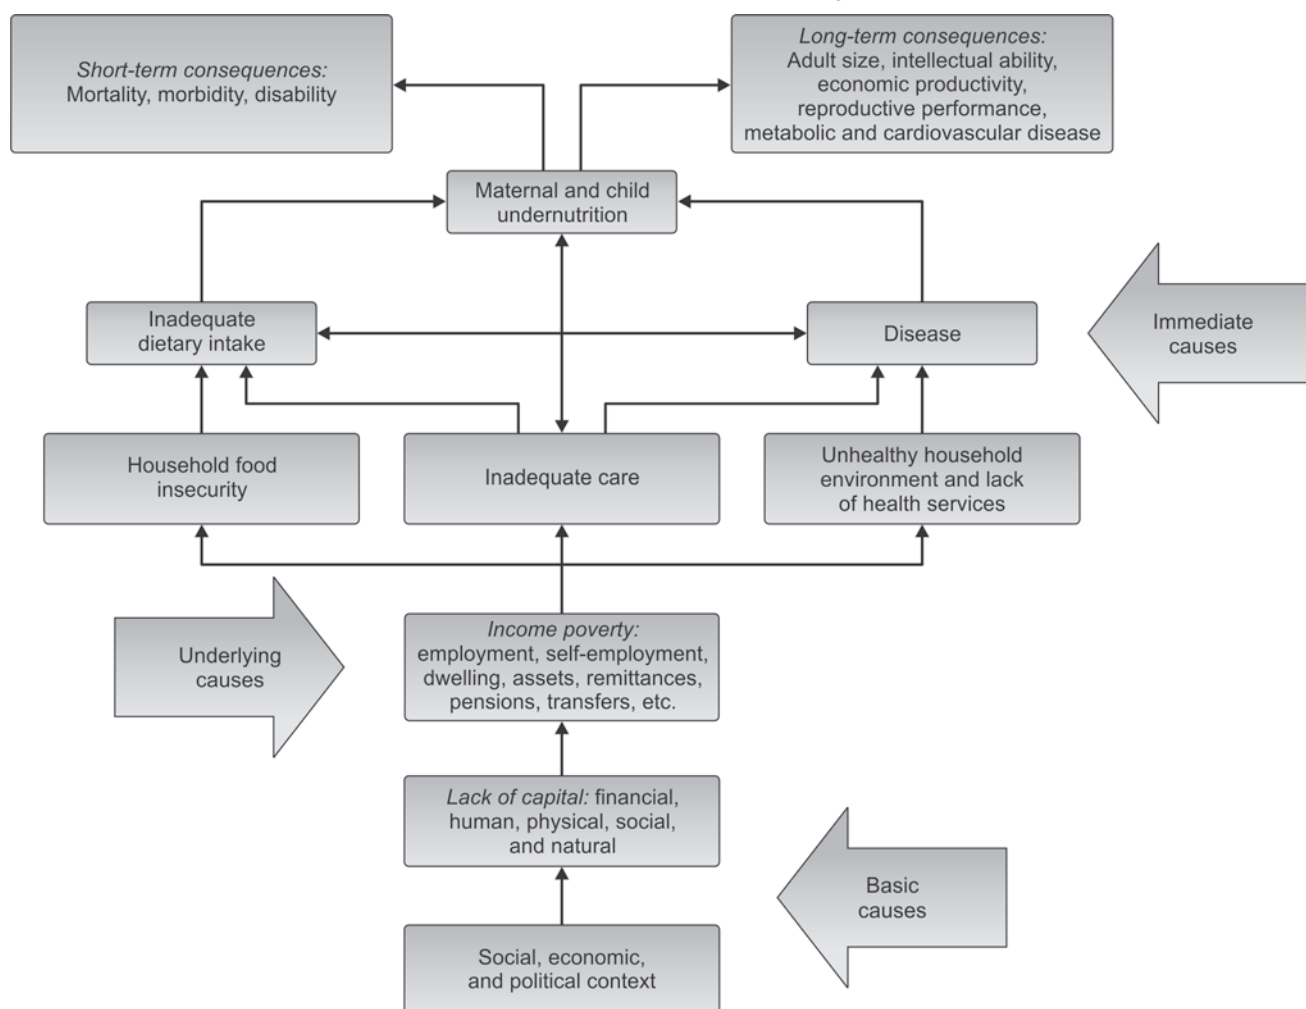

PATHOPHYSIOLOGY AND ADAPTATION

Inadequate energy intake leads to various physiologic adaptations, including growth restriction; loss of fat, muscle, and visceral mass; reduced basal metabolic rate, and reduced total energy expenditure. The biochemical changes in prolonged starvation involve complex metabolic, hormonal, and glucoregulatory mechanisms. Metabolic changes progress from the early phase, where there is rapid gluconeogenesis with resultant loss of skeletal muscle caused by use of amino acids, pyruvate and lactate, to the later protein conservation phase, with fat mobilization leading to

Table 5: WHO classification of malnutrition

	Moderate malnutrition	Severe malnutrition
Symmetrical edema	No	Yes (edematous malnutrition)
Weight for height	SD score between -2 and -3 (moderate wasting)	SD score < -3 (severe wasting)
Height for age	SD score between -2 and -3 (moderate stunting)	SD score < -3 (severe stunting)

Flow chart 1: Framework of the relations between poverty, food insecurity, and other underlying and immediate causes to maternal and child undernutrition and its short-term and long-term consequences

lipolysis and ketogenesis. Major electrolyte changes including sodium retention and intracellular potassium depletion can be explained by decreased activity of glycoside-sensitive energy-dependent sodium pump to increased permeability of cell membranes in kwashiorkor. Some studies suggest that marasmus represents an adaptive response to starvation, while kwashiorkor is a maladaptive response. Aflatoxins have been proposed to have a role in the pathogenesis of kwashiorkor. Reactive oxygen species also have been postulated to have a role in its pathogenesis.

Pathological Effects of Malnutrition in Various Organ Systems (Flow chart 1)

Endocrine System

Reduced levels of tri-iodothyroxine (T3), insulin, insulin-like growth factor-1 (IGF-1), and raised levels of growth hormone and cortisol have been demonstrated in malnutrition. Glucose levels are often initially low, with depletion of glycogen stores. Patients frequently also develop some degree of glucose intolerance of unclear etiology

and are at risk of profound hypoglycemia during the re-nourishment phase.

Immune System

Cellular immunity is affected most because of the atrophy of the thymus, lymph nodes, and tonsils. Changes include reduced CD4 but relatively preserved CD8-T lymphocytes, loss of delayed hypersensitivity, impaired phagocytosis, and reduced secretory immunoglobulin A (IgA). These changes increase the susceptibility of malnourished children to invasive infections.

GI System

Villous atrophy with loss of disaccharidases, crypt hypoplasia and altered intestinal permeability results in malabsorption. Bacterial overgrowth is common with reduced gastric acid secretion. Pancreatic atrophy occurs with resultant fat malabsorption. Fatty infiltration of the liver is common but synthetic functions are usually preserved.

Protein synthesis, gluconeogenesis, and drug metabolism are decreased.

CVS

Cardiac myofibrils are thinned with impaired contractility. Cardiac output is reduced proportionate to weight loss. Bradycardia and hypotension are also common in the severely affected. Intravascular volume is frequently decreased. The combination of bradycardia, impaired cardiac contractility, and electrolyte imbalances predispose these children to arrhythmias.

CNS

Malnutrition has been recognized to cause reductions in the numbers of neurons, synapses, dendritic arborization, and myelinations, all of which result in decreased brain size. Delays in global function, motor function, and memory loss have been associated with PEM, with neonates and infants being most susceptible despite the plasticity of the infant's brain.

Respiratory System

Reduced thoracic muscle mass, decreased metabolic rate may lead to impaired ventilatory response. Malnourished children often develop pneumonia without manifesting any respiratory distress.

CLINICAL FEATURES OF MALNUTRITION

Mild to moderate malnutrition (body weight between 60 and 80 percent of median or $<2SD$ and $>-3SD$) is the most common form of malnutrition and is usually between 9 months to 3 years. Failure to gain weight adequately and weight for age $<2SD$ are usually the earliest sign of malnutrition. Its features include growth failure, increased incidence of infection, decreased activity and sometimes evidence of micronutrient deficiencies like anemia vitamin A and D deficiency. These children also have loss of muscle mass (wasting) indicated by decrease in MUAC but may be reasonably active. They may have increased predisposition to infections which may predispose to further worse bouts of malnutrition.

The two main clinical syndromes of severe malnutrition are marasmus and kwashiorkor, although mixed pictures are also seen frequently. These are differentiated on the basis of clinical findings, with the primary distinction between the two syndromes being the presence of edema in kwashiorkor.

Marasmus

Marasmus is more common than kwashiorkor and is characterized clinically by depletion of subcutaneous fat stores, muscle wasting, and absence of edema. It results

from the body's physiologic adaptation to starvation in response to severe deprivation of calories and other nutrients. It most commonly occurs in children younger than 5 years because of their increased caloric requirements and increased susceptibility to infections. These children often appear emaciated, are weak and lethargic, and have associated bradycardia, hypotension, and hypothermia. Their skin is xerotic, wrinkled, and loose because of the loss of subcutaneous fat but is not characterized by any specific dermatosis. Muscle wasting often starts in the axilla and groin, then thigh and buttocks, followed by chest and abdomen, and finally the facial muscles, which are metabolically less active. The loss of buccal fat pads commonly gives the child an appearance of monkey-like or aged facies in severe cases. In the absence of infection, these children are usually alert with preserved appetite.

Kwashiorkor

The clinical picture is characterized by borderline decrease in body weight (usually between 60 and 80 percent of the expected weight for age), marked generalized edema, dermatoses, hypopigmented hair, distended abdomen, and hepatomegaly. The term sugar baby also has been used to describe these children, as their typical diet is low in protein but high in carbohydrate. Edema usually results from a combination of low serum albumin, increased cortisol, and inability to activate antidiuretic hormone. Hair is usually dry, sparse, brittle, easily pluckable and depigmented, appearing reddish yellow. With adequate protein intake, hair color is restored and may result in alternating bands of pale and normal-colored hair, also known as the flag sign, reflecting periods of poor and good nutrition. Cutaneous manifestations are characteristic and progress over days from dry atrophic skin with confluent areas of hyperkeratosis and hyperpigmentation, which then splits when stretched, resulting in erosions and underlying pale skin. These patchy areas of dark and pale skin give the impression of crazy paving or flaky paint, particularly over limbs and buttocks. Various skin changes in children with kwashiorkor include: shiny, varnished-looking skin (64 percent), dark erythematous pigmented macules (48 percent), xerotic crazy paving skin (28 percent), residual hypopigmentation (18 percent), and hyperpigmentation and erythema. These children also have hepatomegaly, abdominal distension and muscle wasting but tend to retain subcutaneous fat.

Marasmic Kwashiorkor

A child with marasmic kwashiorkor presents with a mixed picture with features of both marasmus and kwashiorkor. Characteristically, these children have concurrent gross wasting and edema and frequently are stunted. They usually have mild hair and skin changes and an enlarged palpable fatty liver.

WHAT IS SEVERE ACUTE MALNUTRITION (SAM)? (TABLE 6)

WHO and UNICEF have recently recommended the use of the term severe acute malnutrition (SAM) and recommended the use of a cut-off for weight-for height of below -3 standard deviations (SD) of the WHO standards to identify infants and children as having SAM. In conventional terminology they would just be referred as severe malnutrition or marasmus (Fig. 3). These groups of children have been separated as they have:

- The highly elevated risk of death compared to those who are above it.
- A higher weight gain when receiving a therapeutic diet compared to their diets, which results in faster recovery.

In simpler terms all children with body weight less than 60 percent of the expected and or nutritional edema should be considered to have severe malnutrition and to be at great risk of death due to any intercurrent illness.

However to our mind SAM is a misnomer as severe malnutrition or marasmus is never acute and develops over weeks and months. However, these children can develop acute complications usually due to a secondary infection to which they are very prone. Further infections in these children are usually very subtle and may cause few or no symptoms. Thus, they do not develop fever or respiratory distress even with the presence of pneumonia. Also infections tend to get very fulminant because of their compromised immunological status. These children are very prone to develop complications like dyselectrolytemia, hypoglycemia and even shock as a consequence of any acute intercurrent illness. It is only in this context (development of severe illness in a rather acute manner) in children with severe malnutrition can the terminology of SAM can be applied. WHO standards for mid-upper arm circumference (MUAC) for age show that in a well-nourished population there are very few children aged 6 to 60 months with a MUAC less than 115 mm. Children with a MUAC less than 115 mm have a highly elevated risk of death compared to those who are above it (Table 6).

Table 6: Diagnostic criteria for SAM in children aged 6 to 60 months

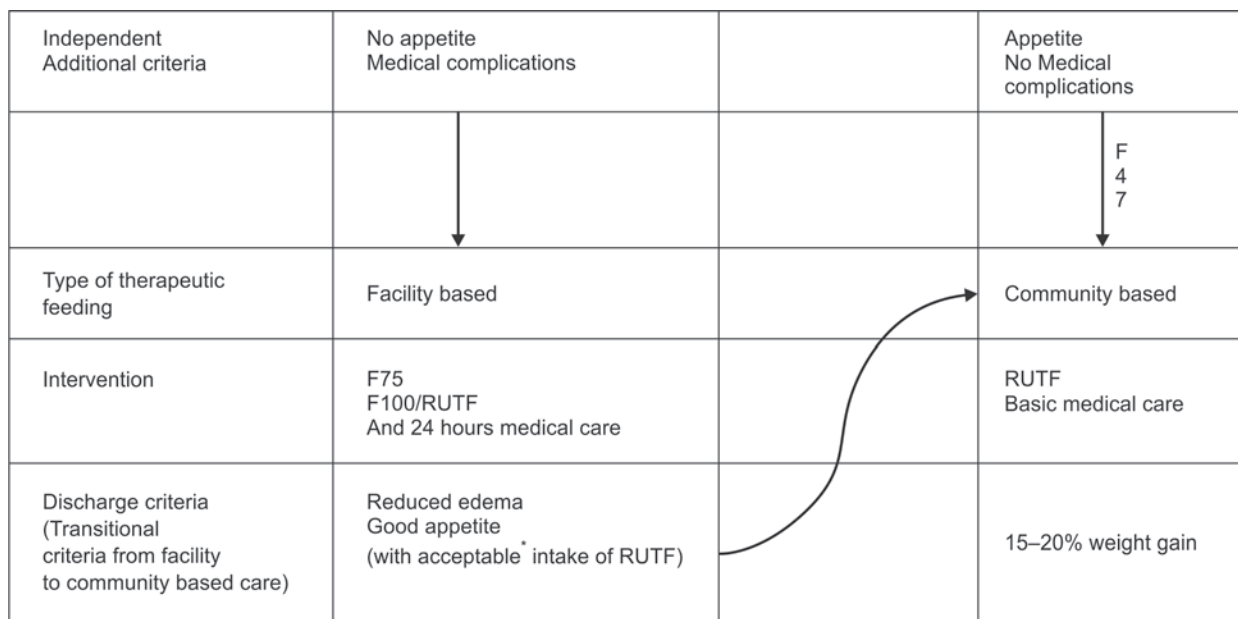

Indicator	Measure	Cut off
Severe wasting**	Weight for height*	<-3 SD
Severe wasting**	MUAC	< 115 mm
Bilateral edema***	Clinical sign	

*Based on WHO standards

, *Independent indicators of SAM that require urgent action

MANAGEMENT OF MALNUTRITION

Periodic weighing and charting on growth charts (road to health chart) is the key to detect early growth faltering or FTT and enables institution of corrective measures at an early stage. Intervention at the community level is usually sufficient for their management. Increasing the energy intake up to 150 kcal/kg/day with frequent energy dense (increased oil content) and the protein intake of 3-3.5 gm/kg/day is usually sufficient. Intercurrent infections need to

* Child eats at least 75% of their calculated RUTF ration for the day

Fig. 3: SAM management (WHO)

be treated promptly. Also it is very essential to maintain adequate nutritional intake during acute illness as food deprivation (mostly iatrogenic) during acute illness is a very important factor in further worsening of the nutritional status. Best measure of the efficacy of treatment is weight gain.

Children with severe malnutrition (body weight <60 percent or <3 SD) with no complications can also be possibly managed in the community but would require very close supervision. In any case if they develop any inter-current illness then they should be promptly hospitalized as they can deteriorate very fast. It should be remembered that decrease in appetite in a marasmic child is very ominous sign for which they need prompt evaluation (usually an infection), hospitalization and management (Flow chart 2).

Initial Assessment of a Severely Malnourished Child

The initial assessment of a severely malnourished child involves a good history and physical examination. The key points to be covered include history of (i) Recent intake of food and fluids; (ii) Usual diet (before the current illness);

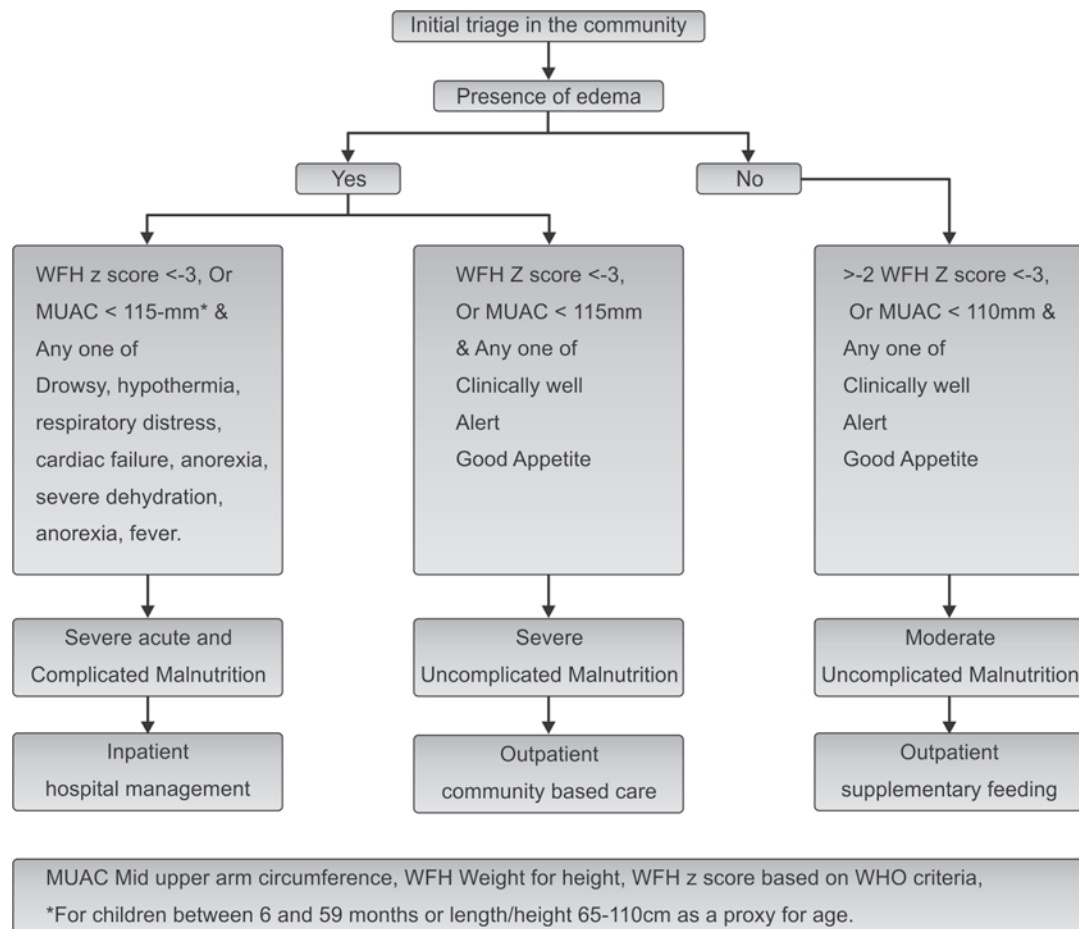

(iii) Breastfeeding; (iv) Duration and frequency of diarrhea and vomiting; (v) Type of diarrhea (watery/bloody); (vi) Loss of appetite; (vii) Fever; (viii) Symptoms suggesting infection at different sites; (ix) Family circumstances (to understand the child's social background); (x) Chronic cough and contact with tuberculosis; (xi) Recent contact with measles and (xii) Known or suspected HIV infection.

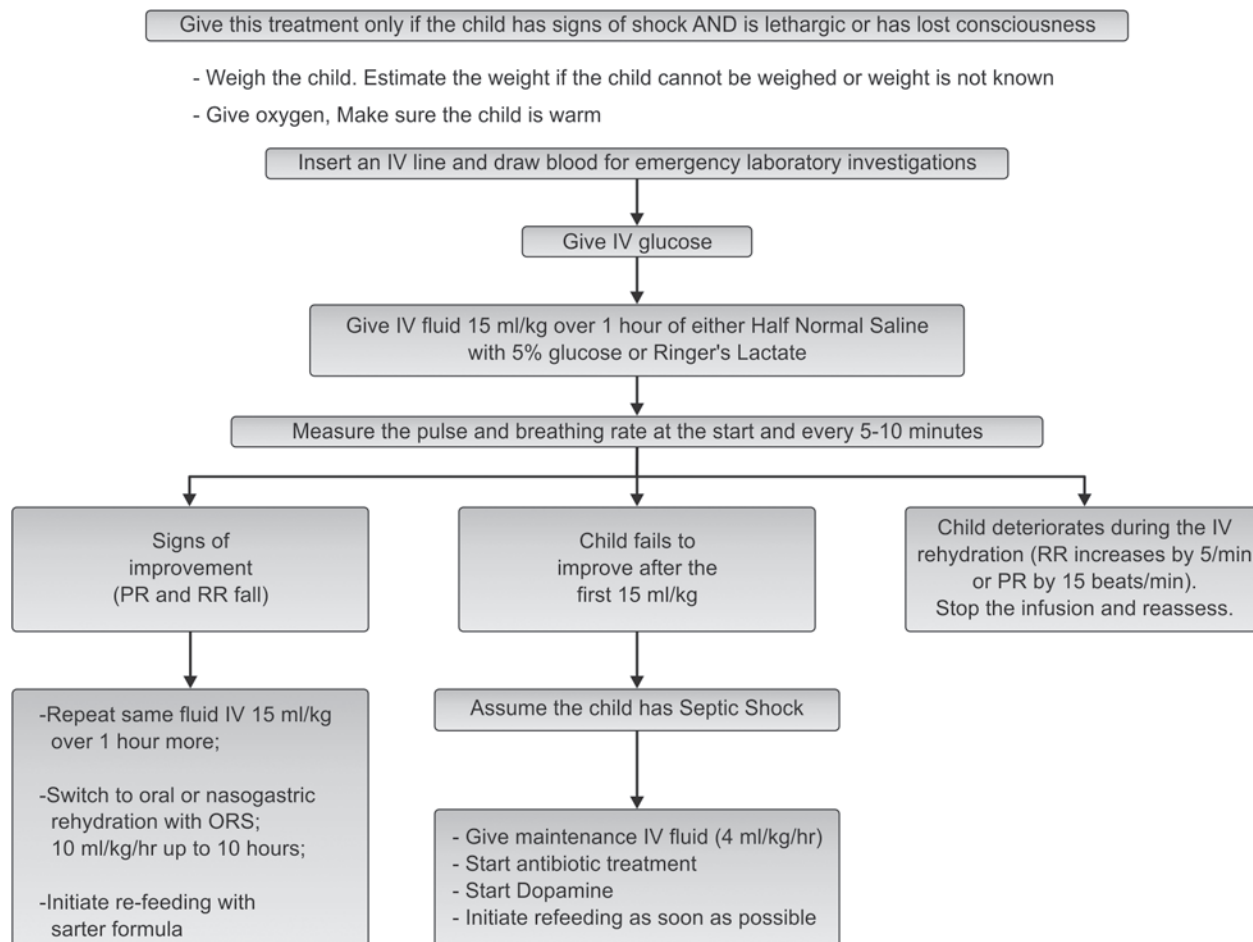

On examination the following points should be looked for:

Anthropometry-weight, height/length, mid-arm circumference; (ii) Signs of dehydration; (iii) Shock (cold hands, slow capillary refill, weak and rapid pulse); (iv) Lethargy or unconsciousness; (v) Severe palmar pallor; (vi) Localizing signs of infection, including ear and throat infections, skin infection or pneumonia; (vii) Fever (temperature $\geq 37.5^{\circ}\text{C}$ or $\geq 99.5^{\circ}\text{F}$) or hypothermia (rectal temperature $< 35.5^{\circ}\text{C}$ or $< 95.9^{\circ}\text{F}$); (viii) Mouth ulcers; (ix) Skin changes of kwashiorkor; (x) Eye signs of vitamin A deficiency and (xi) Signs of HIV infection.

Inpatient treatment of severely malnourished children (WHO Guidelines for the inpatient treatment of severely malnourished children, 2003).

Flow chart 2: The clinicians to decide whether the malnourished child needs hospitalization

Flow chart 3: Management of shock in a child with severe acute malnutrition

The treatment guidelines are divided into ten essential steps as shown below (Fig. 4):

1. Treat/prevent hypoglycemia
2. Treat/prevent hypothermia
3. Treat/prevent dehydration
4. Correct electrolyte imbalance
5. Treat/prevent infection
6. Correct micronutrient deficiencies
7. Start cautious feeding
8. Achieve catch-up growth
9. Provide sensory stimulation and emotional support
10. Prepare for follow-up after recovery.

Step 1: Treat/Prevent Hypoglycemia

All severely malnourished children are at risk of hypoglycemia. There is evidence to suggest association between the hypoglycemia and risk of mortality in severely malnourished children, hence blood glucose should be measured immediately at admission by using glucose estimating reagent paper strips such as dextrostix-reagent strips. Blood glucose level <54 mg/dl or 3 mmol/L is defined as hypoglycemia in a severely malnourished child. If blood

glucose cannot be measured, hypoglycemia should be assumed to be present and treated. Hypoglycemia could be asymptomatic or symptomatic. Symptomatic hypoglycemia manifests as lethargy, unconsciousness or seizures. Sympathetic manifestations of hypoglycemia like pallor and sweating are rare in severe malnutrition but may occur. Peripheral circulatory failure and hypothermia may be a manifestation of hypoglycemia. Hypothermia, infection and hypoglycemia generally occur as a triad. Presence of one should alert for the presence of others.

Treatment Asymptomatic Hypoglycemia

Give 50 ml of 10 percent glucose or sucrose solution (1 rounded teaspoon of sugar in 3½ tablespoons of water) orally or by nasogastric tube. Start feeding 2 hourly day and night (Initially one can give 1/4th of the 2 hourly feed every 30 minutes till the blood glucose stabilizes).

Symptomatic Hypoglycemia

Give 10 percent dextrose iv 5 ml/kg (if unavailable give 50 ml of 10 percent dextrose or sucrose solution by nasogastric

Fig. 4: Time frame for initiating/achieving 10 steps¹¹

tube). Follow with 50 ml of 10 percent dextrose or sucrose solution by nasogastric tube. Start feeding as quickly as possible with the starter F75 diet and then continue the feeds 2 to 3 hourly day and night (Initially one can give 1/4th of the 2 hourly feed every 30 minutes till the blood glucose stabilizes). Start appropriate antibiotics.

Monitoring

If the initial blood glucose was low, repeat an estimation using finger or heel-prick blood after 30 min. If the blood glucose is again low, repeat 50 ml of 10 percent dextrose or sucrose solution (as described above). Blood glucose monitoring may have to continue every 30 min till the blood glucose becomes normal and stabilizes; thereafter, start 2 hourly feeding. In case the body temperature falls (axillary temperature is less than 35°C or rectal temperature is less than 35.5°C) or consciousness deteriorates measure the blood sugar again and act accordingly.

Prevention

The cornerstone of prevention is feeding at regular intervals (2 hourly) starting immediately (if necessary, rehydrate first). Ensure the child is fed regularly throughout the night.

Step 2: Treat/Prevent Hypothermia

All severely malnourished children are at risk of hypothermia due to a lowered metabolic rate and decreased body fat. Children with marasmus, concurrent infections, denuded skin and infants are at a greater risk. Always look for and manage hypoglycemia in a hypothermic child.

Hypothermia is diagnosed if the rectal temperature is less than <35.5°C or 95.5°F. If axillary temperature is less than 35°C or 95°F or does not register on a normal thermometer, assume hypothermia. Use a low reading thermometer (range 29–42°C), if available. Hypothermia can occur in summers as well. Whenever Hypothermia

is present, measure blood glucose and screen for infections.

Treatment

Ensure that the head is also covered well with a scarf or a cap. Feed the child immediately, Clothe with warm clothes and use a warm blanket. Avoid a hot water bottle (Risk of burns followed by hypothermia). Child could also be put in contact with the mother's bare chest or abdomen (skin to skin) as in kangaroo mother care to provide warmth. Treat with appropriate antibiotics.

Step 3: Treat/Prevent Dehydration

IV route is best avoided for rehydration except in cases of shock. It is because of danger of overhydration and possible dyselectrolytemia. The malnourished children may have edema with intravascular dehydration and may develop congestive cardiac failure if overaggressive iv rehydration is used. Use of reduced osmolarity ORS with potassium supplements is preferable. Feeding must be initiated within two to three hours of starting rehydration. Give F75 starter formula on alternate hours (e.g. hours 2, 4, 6) with reduced osmolarity ORS (hours 3,5,7).

Be alert for signs of overhydration (increasing respiratory rate by 5 per min and pulse rate by 15 per min, increasing edema and periorbital puffiness), which can be dangerous and may lead to heart failure. If you find any sign of overhydration, stop ORS immediately and reassess after one hour (avoid the use of diuretics). Stop ORS for rehydration if any four hydration signs are present (child less thirsty, passing urine, tears, moist oral mucosa, eyes less sunken, faster skin pinch).

Step 4: Correct Dyselectrolytemia

Excess body sodium exists even though the plasma sodium may be low in severely malnourished children. Giving high

amounts of sodium could kill the child. In addition, all severely malnourished children have deficiencies of potassium and magnesium; these may take two weeks or more to correct. Edema may partly be due to these deficiencies. Do not treat edema with a diuretic.

Treatment

All severely malnourished children need to be given supplemental potassium at 3–4 mmol/kg/day orally for at least 2 weeks. Potassium can be given as syrup potassium chloride; the most common preparation available has 20 mEq/15 ml. Severe hypokalemia (Serum K^+ < 2.5 mEq or EKG changes with serum K^+ < 3.5 mEq would warrant a K^+ iv bolus of 0.3–0.5 mEq/kg/hr). On day 1, give 50 percent magnesium sulphate (equivalent to 2 mmol/ml). IM once (0.3 ml/kg up to a maximum of 2 ml) Thereafter, give extra magnesium (0.4–0.6 mmol/kg daily) orally. Injection magnesium sulphate can be given orally as a magnesium supplement mixed with feeds. Prepare food without adding salt. Potassium and magnesium can also be supplemented daily by preparing a stock solution of the WHO electrolyte and mineral mix and adding 20 ml of this solution to 1 liter of feed.

Step 5: Treat/Prevent Infection

In severe malnutrition, multiple infections are common and the usual signs of infection such as fever are often absent. Studies have documented high rates of blood stream and urinary tract infections in children with SMN. Investigations may be done for identifying the infections in SMN children, whenever and wherever feasible/available. Broad spectrum antibiotics (ampicillin and Gentamicin/Amikacin) should be used and hiked to ceftriaxone/cefotaxime if no response within 48 hours. Tuberculosis and Malaria should be considered early in the course of infections but empirical therapy in the absence of evidence should be discouraged. Ectoparasite and helminthic infections should be taken care of when the child is stable. Prevention of hospital acquired infections with good hand hygiene practices and good housekeeping practices as in intensive care areas should be encouraged.

Step 6: Correct Micronutrient Deficiencies

All severely malnourished children have vitamin and mineral deficiencies. Micronutrients should be used as an adjunct to treatment in safe and effective doses. Up to twice the recommended daily allowance of various vitamins and minerals should be used.

- Vitamin A orally or im on day 1 unless a dose has been given in the last month.
- Folic acid 5 mg on D1 followed by 1 mg/d.
- Zinc 2 mg/kg/d.
- Copper 0.2 to 0.3 mg/kg/d (multivitamin/mineral commercial preparation).
- Iron 3 mg/kg/d, only once child starts gaining weight; after the stabilization phase (infection free).

Step 7: Initiate Refeeding

Start feeding as soon as possible with a diet which has Osmolarity less than <350 mosm/L, Lactose not more than 2 to 3 g/kg/day, Adequate bioavailability of micronutrients, low viscosity, easy to prepare and socially acceptable and can be adequately stored, cooked and refrigerated. Start cautious feeding as soon as possible as frequent small feeds. Initiate nasogastric feeds if the child is not being able to take orally, or takes <80 percent of the target intake. Recommended daily energy and protein intake from initial feeds is 100 kcal/kg and 1 to 1.5 g/kg respectively. Total fluid recommended is 130 ml/kg/day reduced to 100 ml/kg/day if there is severe, generalized edema. Continue breast feeding *ad lib*. The volume of feeds should be increased gradually while decreasing the frequency of administration. The calories should be increased only after the child is able to accept the increased volume of feeds (Table 7).

Starter Diets

These diets are basically low lactose concentration (diluted milk), energy dense (by addition of oil and sugar and sugar) and protein moderate of good biologic value (milk protein \pm cereal) and reasonable palatability for the initial feeds of severely malnourished children.

Step 8: Achieve Catch-up Growth

Once appetite returns which usually happens in 2 to 3 days higher intakes should be encouraged. The frequency of feeds should be gradually decreased to 6 feeds/day and the volume offered at each feed should be increased. It is recommended that each successive feed is increased by 10 ml until some is left uneaten.

Breast feeding should be continued *ad libitum*. Make a gradual transition from F-75 diet to F-100 (100 kcal/100 ml) diet. The starter F-75 diet should be replaced with F-100 diet in equal amount in 2 days (Tables 8 and 9).

Complementary foods should be added as soon as possible to prepare the child for home foods at discharge. They should have comparable energy and protein concentrations. Once the catch-up diets are well tolerated, Kichri, dalia, banana, curd-rice and other culturally acceptable and locally available diets can also be offered liberally.

Step 9: Provide Sensory Stimulation and Emotional Support

Age appropriate structured play therapy for at least 15 to 30 min/day and principles of tender loving care (TLC).

Table 7: Feeding patterns in initial days of rehabilitation

Days	Frequency	Volume/kg/feed	Volume/kg/day
1–2	2 hourly	11 ml	130 ml
3–5	3 hourly	16 ml	130 ml
6	4 hourly	22 ml	130 ml

- regain appetite by day 4
- start losing edema by day 4
- gain at least 5g/kg/day-by-day 10
Or still has edema on day 10.

Secondary failure to respond is indicated by:

Failure to gain at least 5g/kg/day for 3 consecutive days during the rehabilitation phase.

What is Poor Weight Gain?

- Good weight gain is >10 g/kg/day and indicates a good response. It is recommended to continue with the same treatment.
- Moderate weight gain is 5 to 10 g/kg/day; food intake should be checked and the children should be screened for systemic infection.
- Poor weight gain is <5 g/kg/day and is alarming. Search should be made for underlying cause such as:
 - a. Inadequate feeding
 - b. Specific nutrient deficiencies
 - c. Untreated infections (UTI, Tuberculosis, otitis media, Giardiasis, malaria)
 - d. HIV/AIDS/Celiac disease.

Hospital Discharge Criteria

Severely malnourished children are ready for discharge when the following criteria have been fulfilled:

- Absence of infection.
- The child is eating at least 120 to 130 Kcal/kg/day and receiving adequate micronutrients.
- There is consistent weight gain (of at least 5 g/kg/day for 3 consecutive days) on exclusive oral feeding (at least 15% weight gain). The child is still likely to have a low weight-for-age because of stunting.
- Absence of edema for at least two weeks before discharge.
- Caretakers are sensitized to home care.

It is important to look at the immunization status of the child and try to give age appropriate immunizations prior to discharge.

NUTRITIONAL REHABILITATION PHENOMENON

1. *Benign intracranial hypertension* (Pseudotumor Cerebri) results from over energetic correction in malnourished infants. It is usually self-limiting.
2. *Nutritional recovery syndrome* (Kahn's syndrome) presents with abdominal distension, hepatomegaly, ascites, prominent thoracoabdominal venous network, gynecomastia, parotid enlargement, eosinophilia and splenomegaly.

It is seen in children who are fed with high quantity of protein during the initial stages of treatment. Causative factors may be endocrine disturbances by release of trophic hormones by recovering pituitary gland and increased circulating estrogen levels.

Step 10: Prepare for Follow-up After Recovery

Assessing Response

Response to therapy may be considered inadequate if the child fails to:

3. *Encephalitic like syndrome*: It is seen in 20 percent of the children with kwashiorkor who may become drowsy in initial stages of initiation of nutritional therapy. Most often self-limited. On rare occasions symptoms of basal ganglia dysfunction (tremors, parkinsonian rigidity, bradykinesia and myoclonus) may be present.
4. *Refeeding syndrome*: Clinical manifestations of RFS are a direct result of the electrolyte and hormonal changes that occur as the basal metabolic rate rapidly increases. Once nutrition is reintroduced to a patient who has been starved for an extended period, anabolism begins instantaneously. The body shifts back to carbohydrate metabolism from protein and fat catabolism, and glucose becomes the primary source of energy once again. The increased glucose load, with a corresponding increase in the release of insulin, leads to cellular uptake of glucose, potassium, magnesium, and phosphate. This shift of electrolytes back into the cell causes hypokalemia, hypomagnesemia and hypophosphatemia. Insulin also exhibits a natriuretic effect on the kidneys. Hence, sodium is retained; causing fluid retention and expansion of the extracellular fluid volume. The patient may manifest signs and symptoms of hypophosphatemia, hypokalemia, hypomagnesemia, hyperglycemia, fluid overload, or thiamine deficiency. Should the signs and symptoms of RFS emerge, nutritional support should be stopped immediately. Electrolyte abnormalities should be corrected without delay, and supportive measures should be administered, such as the administration of intravenous thiamine for encephalopathy, iv phosphate supplementation, vasopressors for hypotension, oxygen for respiratory distress, and diuretics for fluid overload. Once these conditions are addressed, feeding can be restarted.

Community Based Therapeutic Care

A new model of delivering care has been proposed, called community-based therapeutic care (CTC), which is designed to address the limitations of inpatient care with the advantages of CTC programs use decentralized networks of outpatient treatment sites (usually located at existing primary health-care facilities), small inpatient units (usually located in existing local hospital facilities) and large numbers of community-based volunteers to provide case detection and some follow-up of patients in their home environments. Patients with severe malnutrition, with good appetite, and without medical complications are treated in an outpatient therapeutic program (OTP) that provides ready-to-use therapeutic food (RUTF) and medicines to treat simple medical conditions.¹¹ Home-based management has many advantages as the children have reduced exposure to hospital acquired infections and receive continuity of care after discharge. It also benefits by increasing the time available to mothers to spend with family and reduces the risk of possible neglect of siblings.¹²

Ready to Use Therapeutic Foods (RUTF)

RUTF are soft or crushable foods that can be consumed easily by children from the age of six months without adding water. RUTF have a similar nutrient composition to F100, which is the therapeutic diet used in hospital settings. But unlike F100, RUTF are not water-based, meaning that bacteria cannot grow in them. Therefore these foods can be used safely at home without refrigeration and even in areas where hygiene conditions are not optimal. Imported RUTF may need a cautious approach in India as our administrative system is porous and there is a chance of commercial exploitation of malnutrition.¹² Recent studies have shown effectiveness of locally produced RUTF in the treatment of mild and moderate undernutrition in the community.¹³

PREVENTION OF MALNUTRITION

Interventions to prevent childhood undernutrition and its adverse outcomes include promotion of breastfeeding; strategies to promote complementary feeding, provision of food supplements; micronutrient interventions; and general supportive strategies to improve family and community nutrition.

The measures to prevent malnutrition can be stratified at national, community and family level. The adoption of National Nutrition Policy by the government has been a significant achievement at the national level. Various programs directed against general malnutrition like integrated child development services program (ICDS), National Program of Mid-day Meals in Schools, National Nutrition Anemia Prophylaxis Program and many others have been launched or strengthened in pursuance of these policies.

Promotion of education and literacy in the community with special focus on health and nutrition education should be implemented as a key measure at the community level. Exclusive breast feeding for first 6 months of life, introduction of complementary foods at 6 months and periodic growth monitoring on growth cards should be vigorously promoted and encouraged. Primary health care packages should be made available to all sectors of the population and iatrogenic restriction of feeding in fevers and diarrhea should be discouraged. Regular growth monitoring should be included in all child health programs to enable early detection of FTT and institution of appropriate measures. Adequate time should be allowed between two pregnancies with promotion of family planning programs to limit the family size.

Above interventions should be supplemented by improvements in the underlying determinants of undernutrition, such as poverty, illiteracy, disease burden, and lack of women empowerment.

SUMMARY

Malnutrition is a very common entity in developing countries with short term, medium term and long term

consequences to family, society and world. WHO classification of malnutrition is the most widely used classification in children. Protocol based care of hospitalized children with severe complicated malnutrition should be encouraged with additional stress on stimulation, emotional support and follow up. Early detection and nutritional rehabilitation of malnourished children in the community is of outmost importance. Locally produced cost effective RUTF is the need of the hour.

ASSESSMENT OF GLOMERULAR FUNCTION

Glomerular filtration rate (GFR) is the best indicator of renal function in children and adolescents and is critical for diagnosing acute and chronic kidney impairment. Accurate means of determining GFR is essential for determining doses of fluids and medications, monitoring for nephrotoxicity caused by antibiotics and chemotherapeutic agents, and assessing progression of renal disease.¹ The level of GFR is the product of the single nephron GFR multiplied by the number of functioning nephrons in both kidneys. The total GFR can be used as an index of functioning renal mass.

Serum Creatinine

Creatinine is an amino acid derivative derived from the metabolism of creatine phosphate in muscle, and is usually produced at a fairly constant rate by the body (depending on muscle mass). It is chiefly excreted by glomerular filtration; hence serum creatinine levels reflect changes in GFR. Normal levels of serum creatinine range from 0.2 to 0.5 mg/dl in older children. However, its levels are low when the muscle mass is decreased (malnutrition, muscle wasting) and drugs such as cimetidine, trimethoprim influence its renal tubular secretion.

Serum Cystatin C

Cystatin C is a low molecular weight protein member of cysteine protease inhibitors. It is produced by all nucleated cells and exhibits a stable production rate. Cystatin C is freely filtered by the glomerulus and completely reabsorbed and catabolized by the renal tubules. There are no sites of extra-renal metabolism. Hence serum levels of this product have been proposed as a marker of GFR.² Normal serum levels in adults are ≤ 0.95 mg/L and children >1 years show adult levels. Serum cystatin C levels are not influenced by muscle

mass, age or gender but the estimation is kit based (EIA/immunoturbidimetry) and is expensive.

Blood Urea

Urea is derived from the protein metabolism and synthesized in the liver. Urea is readily filtered, reabsorbed as well as secreted by the tubules. Blood urea levels and excretion are affected by dietary protein intake and state of hydration. However, in a steady state blood urea may not rise beyond upper range of normal (40 mg/dl) even when 75 percent of renal function is lost.

METHODS FOR ESTIMATING GLOMERULAR FILTRATION RATE

Glomerular filtration rate (GFR) can be quantified by measuring the clearance rate of a substance from the plasma. The substance, often referred to as the marker, can be endogenous or exogenous. It must have a stable plasma concentration and should be filtered, not reabsorbed, secreted, synthesized or metabolized by the kidney so that the filtered substance equals the excreted substance. Measurement of GFR is the best clinical test for estimation of functioning renal mass. Knowledge of GFR enables the clinician to prescribe fluids and solutes, determine the progression of kidney disease, predict the development of end-stage renal disease (ESRD), and appropriately dose medications excreted by the kidney.

Inulin Clearance¹

Inulin is considered an ideal marker and the gold standard for measuring GFR. The classic (standard) inulin clearance requires an intravenous priming dose of inulin, followed by a constant infusion to establish a steady-state inulin plasma concentration. After an equilibration for about 45 minutes, serial urine samples are collected every 10 to 20 minutes

through an indwelling bladder catheter or voluntary voiding. The use of inulin clearances has a number of limitations. First, some children may not be toilet trained and are unable to provide accurate collections of timed urine. Second, urologic problems are common causes of chronic kidney disease in infants and young children. The collection of timed urine in such patients is difficult and fraught with error. Third, technical difficulties encountered in performing inulin infusions, and reaching a steady state of inulin distribution, are common. Lastly, inulin is not currently readily available. These problems have rendered the standard inulin clearance to be impracticable in children.

Creatinine Clearance²

Creatinine is an amino acid derivative produced in muscle cells. It is freely filtered and about 10 percent of the creatinine found in urine is secreted by the proximal tubules. Tubular secretion varies among and within individuals. Endogenous creatinine clearance provides an acceptable measurement of GFR for clinical purposes and is calculated by the following equation:

$$\text{Ccr} = \text{Uc} \times \text{V}/\text{Scr}$$

where Ccr is creatinine clearance, Ucr is urine creatinine concentration, V is flow rate of urine in ml/minute, and Scr is serum creatinine. The creatinine clearance is normalized to body surface area (BSA) by being multiplied by the factor 1.73/BSA in square meters. Urinary creatinine excretion should generally be approximately 20 mg/kg per day in children over 3 years of age and values less than this indicates incomplete urine collection.

However, creatinine clearance overestimates the actual GFR (due to presence of non-creatinine chromogens, normally present in plasma are measured along with creatinine giving a falsely high value to serum creatinine and this partly compensates for the tubular secretion of creatinine). The administration of cimetidine to patients with renal disease causes a decrease in tubular creatinine secretion, resulting in a creatinine clearance that approximates the level of true GFR. While the cimetidine protocol is a convenient, inexpensive procedure for estimating GFR, failure to document bladder emptying by ultrasound, lack of toilet training, and the presence of urologic conditions can cause inaccuracies in the results because of problems in urine collection.

Nuclear GFR¹

Glomerular filtration rate (GFR) can be accurately measured using a radioactive tracer such as chromium 51 (⁵¹Cr) EDTA or technetium 99 m (^{99m}Tc) DTPA in children. The most accurate method is based on the plasma disappearance curve after a single bolus injection. The clearance of the radiotracer is given by the injected dose divided by the area under the curve. The initial 'fast'

curve represents the diffusion of the radiotracer in its distribution volume, whereas the late, slow exponential curve represents its renal clearance. The two compartment model requires serial blood sampling to obtain an accurate plasma disappearance curve. A major limitation of these methods is presence of significant edema in which case disappearance of the tracer into an expanded ECF volume will artifactually elevate the calculated GFR. Infiltration of the radiotracer at the injection site can also cause artifactual elevation of GFR. The effective dose of radiation is small.

Equations Predicting Glomerular Filtration Rate (GFR)

For reasons of convenience, GFR is usually estimated from plasma creatinine using prediction equations. Although the Schwartz formula ($\text{GFR} = k \times \text{height}/\text{plasma creatinine}$) is widely used equation in children,³ several reports suggest that this formula overestimates GFR, if originally proposed values of k (constant) are used.² Various studies have reported k values ranging from 0.41 to 0.55 that better estimated GFR than the original k of 0.55.² This is primarily due to more accurate measurement of levels of plasma creatinine, using methods other than those used previously. The equation is also considered unreliable in malnourished children and in anorectic adolescents.² In view of these considerations, it has been suggested that the value of k should be locally derived, taking into consideration the method for estimating creatinine and the nutritional status of the population.² Using the enzymatic method of creatinine estimation, CKiD study recently proposed a new k value of 0.413 for the height/creatinine formula.⁴ However, this might not apply to centers that measure creatinine by non-enzymatic methods and have patients with lower height percentiles as compared to children in the CKiD study. We have derived a new k , for estimating GFR using height and creatinine in children with CKD (Table 1). Developing countries that use kinetic Jaffe method for estimating serum creatinine instead of enzymatic method and ^{99m}Tc-DTPA for measuring GFR could use a k value of 0.42 in the absence of locally derived k value.

The intrinsic biological variability in the GFR and physiological variability in the production and in the extraglomerular elimination of creatinine would mean that even the estimates from a perfect GFR formula would differ substantially from the true GFR. Additionally, these GFR estimating formulae are not accurate when GFR is rapidly changing, such as in critically ill children or in acute renal failure. Therefore, when precise GFR estimate is needed for an individual patient for decisions such as timing for pre-emptive transplant or dosing of chemotherapeutic drugs, invasive but accurate radionuclide GFR measurement would be justified.

Table 1: Equations for predicting GFR (ml/min/1.73 m²) in children¹

Reference	Formula
<i>Creatinine based</i>	
Original Schwartz ³	$0.55 \times \text{ht(cm)}/\text{Scr}$
CKiD study ⁴	$0.413 \times \text{ht(cm)}/\text{Scr}$
AIIMS, Delhi	$0.42 \times \text{ht(cm)}/\text{Scr}$
Léger ⁵	$(0.641 \times \text{Wt})/\text{Scr} \times (0.00131 \times \text{Ht}^2)/\text{Scr}$
<i>Cystatin based</i>	
Filler	$91.62 \times (\text{cysC})^{-1.123}$
Grubb	$84.69 \times (\text{cysC}) \times 1.680 \times 1.384$ if <14 years
<i>Combined cystatin and creatinine</i>	
CKiD study ⁴	$39.1 \times [\text{ht(m)}/\text{Scr}]^{0.516} \times [1.8/\text{cysC}]^{0.294} \times [30/\text{BUN}]^{0.169} \times 1.099^m \times [\text{ht(m)}/1.4]^{0.188}$

ht, height; Wt, weight (kg); Scr, serum creatinine (mg/dl); m, meter; cysC, cystatin C (mg/L); BUN, blood urea nitrogen (mg/dl)

Several equations have been derived using cystatin C for estimation of GFR in both adults and children (Table 1).¹ Recently, a complex equation that includes serum creatinine, cystatin C and blood urea was derived by CKiD study which predicted the measured GFR best; however the mathematical complexity of the equation precludes its bedside use in clinical practice.⁴

ASSESSMENT OF RENAL TUBULAR FUNCTION

Tubular Reabsorption of Phosphate

The tubular reabsorption of phosphate (TRP) is the fraction (or percent) of filtered phosphorous that is reabsorbed by renal tubules. It is useful in assessing hypophosphatemia. It is expressed as [100 - fractional excretion of phosphorous (FEP)], where

$$\text{FEP} = \frac{\text{urine phosphorous} \times \text{serum creatinine} \times 100}{\text{serum phosphorus} \times \text{urine creatinine}}$$

Normally TRP ranges between 85 and 95 percent. It is reduced in proximal tubular defects, hypophosphatemic rickets and hyperparathyroidism. It is also influenced by GFR and dietary intake. Hence, tubular maximum of phosphorus corrected to the GFR (TmP/GFR) is more appropriate measure of renal phosphate handling as it is independent of dietary phosphorous intake, tissue release of phosphorous and GFR. Tubular maximum of phosphorus corrected to the GFR represents the blood concentration above which most phosphate is excreted and below which most is reabsorbed.⁶ The normal TmP/GFR ranges between 2.8 and 4.4 mg/dl. It can be derived from TRP and plasma phosphorous using Bijvoet nomogram.⁷ However, studies in children have demonstrated that Bijvoet nomogram results in overestimation of TmP/GFR.⁸ This is because Bijvoet nomogram has been traditionally calculated by loading fasting adult patient with

phosphate. The threshold in adults is lower than in children and also children do not demonstrate the phosphate splay (non-linear increase in phosphate reabsorption to its maximum) found in fasting adults. It is suggested that TmP/GFR should be used in the pediatric population rather than nomogram. The former represents tubular phosphate reabsorption under fasting or non-fasting conditions without phosphate load.

$$\text{TmP/GFR} = \text{SP} - \text{UP} \times \text{Scr/Ucr}$$

where, SP is serum phosphate, UP is urine phosphate, Scr is serum creatinine and Ucr is urine creatinine.

Fractional Excretion of Sodium

Fractional excretion of sodium (FeNa) is the percentage of the sodium filtered by the kidney which is excreted in urine. It is calculated as:

$$\text{FeNa} = \frac{\text{urine sodium} \times \text{plasma creatinine} \times 100}{\text{plasma sodium} \times \text{urine creatinine}}$$

It is useful for evaluation of acute kidney injury in order to determine if hypovolemia is a cause of renal dysfunction when FeNa is below 1 percent. Higher values (FeNa >1%) suggest sodium wasting due to intrinsic renal failure. Fractional excretion of sodium is affected by diuretics, since many diuretics act by altering the kidney handling of sodium.

Transtubular Potassium Gradient⁹

Potassium is secreted in late distal and cortical collecting tubules. Transtubular potassium gradient (TTKG) reflects potassium secretory process in distal and cortical collecting tubules. It is calculated as

$$\text{TTKG} = \frac{\text{urine K}^+/\text{serum K}^+ \times \text{serum osmolality}}{\text{urine osmolality}}$$

Urinary sodium should be greater than 25 mEq/L to ensure that insufficient sodium delivery is not limiting the potassium secretion. Urine osmolality should exceed serum osmolality since luminal K^+ concentration is affected by water removal in medullary segments. Transtubular potassium gradient (TTKG) is a good indicator of aldosterone activity in presence of normal renal functions. Transtubular potassium gradient (TTKG) is expected to be more than 7 during hyperkalemia and value below 7 indicates inadequate aldosterone effect.

ASSESSMENT OF URINARY ACIDIFICATION

Urine pH

Urine pH is an estimate of the number of free H^+ ions in the urine which are secreted in response to metabolic acidosis. The presence of alkaline urine during metabolic acidosis suggests defective renal acidification, as in distal renal tubular acidosis (RTA). However, alkaline urine may also be found in patients with metabolic acidosis due to extrarenal disorders, as in acute or chronic diarrhea.

Urine Anion Gap¹⁰

Urine anion gap (UAG) is the difference between concentration of principal urinary cations (sodium + potassium) and anion (chloride). Hence, it gives an estimate of unmeasured cations and anions, which normally include ammonium and bicarbonate. Since, bicarbonate is mostly reabsorbed, it is chiefly a measure of ammonium excretion. A positive UAG suggests a low urinary NH_4^+ (e.g. renal tubular acidosis). A negative UAG suggests a high urinary NH_4^+ (due to obligate chloride excretion with ammonium).

Bicarbonate Loading Test¹¹

This test is useful in differentiating proximal and distal renal tubular acidosis (RTA) by assessing fractional excretion of bicarbonate ($FeHCO_3$). Fractional excretion of bicarbonate is a marker of proximal tubular handling of bicarbonate. The proximal tubule normally reabsorbs almost all filtered bicarbonate (fractional excretion below 5%). A value greater than 15 percent indicates proximal RTA while levels are in the normal range in distal RTA. The fractional excretion of bicarbonate should be calculated only after adequate alkalinization. Sodium bicarbonate is administered in a dose of 3 to 5 ml/kg for 4 to 5 days till urine pH exceeds 7.4 or blood bicarbonate level is between 23 to 26 mEq/L (Table 2).

$$\text{Fractional excretion} = \frac{\text{urine bicarbonate} \times \text{plasma creatinine} \times 100}{\text{urine creatinine} \times \text{plasma bicarbonate}}$$

Urine to Blood CO_2 Difference

Based on the observation that urinary CO_2 excretion is an indicator of H^+ secretion, urine to blood CO_2 difference is considered a satisfactory index of distal renal acidification. In the presence of normal blood bicarbonate, low urine to blood CO_2 difference (<10 mm Hg) suggests distal RTA; the levels are normal in proximal RTA (>20 mm Hg). It is necessary that the difference be determined after adequate alkalinization.

Ammonium Chloride Loading Test

This test is used to confirm distal RTA (Type I), in which there is failure of hydrogen excretion by distal renal tubules. Administration of ammonium chloride induces metabolic acidosis to which normal kidney responds with

Table 2: Tests for assessment of renal tubular function

Test	Function assessed	Indications	Result	Interpretation
Fractional excretion of sodium	Sodium excretion	Prerenal failure Renal salt wasting	$<1\%$ $>2.5\%$	Renal hypoperfusion, Intrinsic renal failure
Transtubular potassium gradient	Potassium excretion	Hyperkalemia	<7	Aldosterone deficiency/ resistance
Tubular reabsorption of phosphate, TmP/GFR	Phosphate excretion	Hypophosphatemic rickets, Fanconi syndrome	TRP $<85\%$, GFR <2.8 mg/dl	Phosphaturia
Bicarbonate loading test	Bicarbonate excretion	Renal tubular acidosis	$Fe HCO_3 <5\%$ $>15\%$	Normal Proximal RTA
Urine –Blood CO_2	H^+ secretion		$<10\%$ $>20\%$	Distal RTA Normal
Ammonium chloride loading, Furosemide fludrocortisone test	Proton secretion	Renal acidification (distal RTA)	Urine pH >5.5	Distal RTA
Water deprivation test	ADH induced water reabsorption	Diabetes insipidus		See Table 3

Table 3: Interpretation of water deprivation test

Condition	Urine osmolality (mOsm/kg) on water deprivation	Change in osmolality with dDAVP (mOsm/kg)
1. Normal	>800-900	Minimal/no increase
2. Complete central DI	<300	Substantial increase
3. Partial central DI	300-800	Increase of >10%
4. Nephrogenic DI	<200-300	Minimal or no increase
5. Primary polydipsia	>500	Minimal or no increase

maximal urinary acidification. Ammonium chloride is given orally in a dose of 0.1 to 0.15 g/kg over 30 to 45 minutes usually with fruit juice and is followed by liberal fluid intake. Urine pH is measured every hour over next 6 hours followed by blood pH. Failure to lower the urine pH below 5.5 despite severe acidosis ($\text{TCO}_2 < 15$), suggests distal RTA.

Furosemide Fludrocortisone Test¹²

This test is an easy, effective, and well tolerated alternative to standard ammonium chloride urine acidification test for diagnosis of distal RTA. A baseline urine sample is collected after which the patient is given 1 to 2 mg/kg of furosemide and 0.1 to 0.3 mg of fludrocortisone. This leads to increase distal sodium delivery, principal cell sodium reabsorption and alpha intercalated cell proton secretion. Urine is collected hourly for 6 hours. Patients with distal RTA fail to lower pH <5.3 while normal controls lower pH<5.3 after 3 hours.

ASSESSMENT OF URINARY CONCENTRATION¹³

Urine Osmolality

It is a measure of concentration of the urine and is determined by the number of particles in the solution. The maximum urinary concentration capacity varies with age; while the maximum urine osmolality in neonates is about 700 mOsm/kg, the osmolality in older children and adults can rise up to 1200 mOsm/kg. The test is useful for identifying syndrome of inappropriate antidiuretic hormone secretion (SIADH) (urine osmolality >200 mOsm/kg, low serum sodium, urine sodium >20 mEq/L, for differentiating prerenal from renal failure (high urine osmolality is consistent with prerenal impairment) and, for identifying and diagnosing diabetes insipidus (DI).

Urine Specific Gravity

It measures the kidney's ability to concentrate/dilute urine in relation to plasma and is determined both by the number and the size of particles in the solution. In most cases, it varies with the osmolality, with specific gravity rising by 0.001 for every 35 to 40 mOsm/kg increase in osmolality. But this relationship is altered when there are appreciable

quantities of larger molecules in urine, e.g. glucose, radio contrast, antibiotics. The normal specific gravity in human urine ranges from 1.003 to 1.030 and is measured by hydrometer.

Urinary Concentration Test

It is useful in a setting of polyuria to differentiate central, nephrogenic diabetes insipidus (complete and incomplete forms) and psychogenic polydipsia. It is not done if the first morning void has an osmolality above 700 mOsm/kg.

Water Deprivation Test

No fluid is allowed after dinner. The bladder is emptied at 8 am, and all the subsequent urine specimens are collected. Water deprivation is stopped if weight loss is more than 5 percent or until three consecutive hourly urine osmolality values are within 10 percent of each other. Normal children can achieve a urine osmolality above 900 mOsm/kg. The interpretation of water deprivation test is summarized in (Table 3).

Vasopressin Test¹⁴

This test is used to confirm lack of renal response in nephrogenic diabetes insipidus. dDAVP (desmopressin) is administered nasally (5-10 microgram in neonates/infants, 20 microgram in children) or by an intramuscular injection (0.4-1 microgram in infants and young children, 2 microgram in older children). Hourly urine collection is done over the next 2 to 3 hours.

Response of primary polydipsia to dDAVP resembles nephrogenic diabetes insipidus (NDI), except that basal ADH levels are low compared with elevated levels present in NDI. Also, after prolonged restriction of fluid intake, normal concentrating ability returns within several weeks.

Urinary Tract Infections: Current Recommendations

Aditi Sinha, Arvind Bagga

INTRODUCTION

Urinary tract infections (UTIs) are a cause of significant morbidity in childhood, affecting 3 to 10 percent girls and 1 to 3 percent boys and accounting for a proportion of “occult” bacterial infections in febrile infants. A proportion of children with UTI have an underlying urinary tract anomaly, most often vesicoureteric reflux (VUR). In these individuals, UTI may predispose to renal scarring (reflux nephropathy), an important cause of hypertension and chronic renal failure later in life.

Over the last few years, various expert groups have proposed guidelines for the evaluation and management of UTI.¹⁻³ This review focuses on the current evaluation and management of UTI, broadly conforming to the current recommendations of the Indian Society of Pediatric Nephrology.³

When to Suspect UTI?

The symptoms of UTI in young children are nonspecific. Unexplained fever may be the only symptom in young children, and UTI account for 3 to 5 percent cases of pyrexia of unknown origin.^{1,4-5} When UTI occurs during early childhood, a setting of VUR, urinary tract obstruction or systemic sepsis is often present. The risk of UTI is similar in boys and girls during infancy, and is thereafter higher in girls.^{5,6} Older children present with fever, dysuria, urgency, frequency and abdominal or flank pain. Adolescents may have symptoms restricted to the lower urinary tract.

Renal parenchymal involvement may be indicated by fever, chills and rigors and flank pain. It is often difficult to distinguish between infection localized to the bladder (cystitis) and upper tracts (pyelonephritis). This distinction is also not necessary since radionuclide imaging shows that almost 70 to 75 percent of UTI in children below 5 years of age involve the kidney and upper tracts.⁶ UTI in children is thus always considered to involve the upper tract and should be treated promptly to avoid renal parenchymal injury.

DEFINITION

The diagnosis of UTI is based on the growth of significant number of organisms of a single species in the urine, in the presence of symptoms. The number of organisms required to be present to define UTI depends on the site from which urine has been collected. Significant bacteriuria is defined as a colony count of $>10^5$ /ml of a single species of bacteria in a midstream clean catch sample. In samples taken by urethral catheterization, a colony count of $>5 \times 10^4$ colony forming units (CFU)/ml, and on suprapubic aspirates any pathogens are considered significant.³

The time the urine resides in the bladder (bladder incubation time) is an important factor affecting the magnitude of the colony count. In its recent recommendations, the American Academy of Pediatrics recommends that the presence of 50,000 CFUs per ml of a single urinary pathogen should be considered “significant” in infants and children below 2 years, except for commensals such as *Lactobacillus* spp, coagulase-negative staphylococci, and *Corynebacterium* spp.²

The occurrence of significant bacteriuria in absence of symptoms is termed *asymptomatic bacteriuria*.

The distinction between simple and complicated UTI is important for determining the choice of therapy.³ Complicated UTI is diagnosed in the presence of high fever ($>39^\circ\text{C}$), systemic toxicity, persistent vomiting, dehydration, renal angle tenderness or raised creatinine. Patients with low grade fever, dysuria, frequency and urgency, and absence of symptoms of complicated UTI are considered to have simple UTI.

DIAGNOSIS

History regarding prior episodes of UTI, and bowel and bladder habits should be elicited. Important components of clinical evaluation include assessment of hydration,

ability to retain oral intake, signs of systemic toxicity and blood pressure.

Features that suggest an underlying abnormality include urinary incontinence; history of surgery for meningomyelocele or anorectal malformation; poor urinary stream or straining at micturition; palpable kidney(s) or distended bladder; tight phimosis or vulval synechiae; and neurological deficit in lower limbs.³ History may suggest bowel bladder dysfunction, in form of constipation or impacted stools, infrequent (<3 times) or frequent (>8 times) daytime voiding, straining during micturition and holding maneuvers to postpone voiding, e.g. vincent curtsy or squatting.

Investigations

While urinalysis enables a presumptive diagnosis of UTI and facilitates initiation of empirical treatment, the diagnosis of UTI must be confirmed by urine culture.

Urinalysis

Leukocyturia is considered significant if microscopy shows >10 leukocytes per mm³ in a fresh uncentrifuged sample, or >5 leukocytes per high power field in a centrifuged sample. The absence of pyuria in children with UTI is rare. However, the detection of leukocyturia in absence of significant bacteriuria is not sufficient to diagnose a UTI.^{3,7}

Rapid dipstick based tests, which detect leukocyte esterase and nitrite, are useful in screening for UTI. A combination of these tests has moderate sensitivity and specificity for detecting UTI in children, and is diagnostically as useful as microscopy.^{2,8} However, since the conversion of dietary nitrates to nitrites by bacteria requires approximately 4 hours in the bladder, a nitrite test has poor sensitivity for detection of UTI, particularly in infants, who empty their bladders frequently.² Similar to pyuria, false-positive results on leukocyte esterase test are common with various conditions other than UTI, including fever of any cause and vigorous exercise.²

The presence of any bacteria in a fresh, Gram stained specimen of uncentrifuged urine correlates with 10⁵ CFU/ml in culture. Enhanced urinalysis is the combination of the counting chamber assessment of pyuria and Gram staining of uncentrifuged urine. When a threshold of at least one gram-negative bacillus in 10 oil immersion fields is used for assessment, enhanced urinalysis has greater sensitivity, specificity, and positive predictive value than does the standard urinalysis.⁹

Urine Culture

A clean catch midstream sample is advised for urine culture in toilet-trained children.⁵ It is sufficient to clean the

genitalia with soap and water prior to sample collection; antiseptic washes and strong soaps should be avoided. The use of a urine collection bag, in infants, applied to the perineum may be falsely positive in 85 percent. Hence, in infants the specimen should be obtained by suprapubic aspiration or transurethral catheterization. Urine specimen for culture should be processed promptly and plated within an hr of collection. If delay of more than 2 hours is anticipated, the specimen is stored at 4° C for up to 12 to 24 hours.²

Nearly 90 percent of the first UTI and 70 percent of recurrent infections are caused by *Escherichia coli*; *Klebsiella*, *Staphylococcus epidermidis* and *Streptococcus fecalis* are occasionally incriminated. UTI following instrumentation and nosocomial infections may be due to *Proteus* and *Pseudomonas*. Fungal UTI should be suspected in hospitalized newborns and infants who are immunocompromised or have received prolonged parenteral antimicrobials. Tuberculosis of the urinary tract is rare in children.⁵

Other Investigations

Children with complicated UTI should be evaluated with complete blood counts, serum creatinine and blood culture.

TREATMENT

Treatment of UTI should be initiated promptly to prevent potential renal parenchymal injury. Empiric therapy is started once a sample for culture has been taken.

Differentiation of acute pyelonephritis from cystitis is not necessary. Except for afebrile adolescents with chiefly lower tract symptoms, all children with UTI should be treated as for pyelonephritis. The mode of therapy depends on the age and whether the UTI is complicated or uncomplicated.

Parenteral Therapy

Infants below 3 months of age and children with complicated UTI should be treated with parenteral antibiotics. The choice of antibiotic is guided by local sensitivity patterns. A third generation cephalosporin (cefotaxime or ceftriaxone) is preferred, but therapy with a single daily dose of aminoglycoside is as effective (Table 1).¹⁰ A single antimicrobial is used in community acquired infections, and combinations used in more sick patients. The treatment is modified once results of antimicrobial sensitivity are available.

Once oral intake improves and symptoms abate, therapy is switched to an oral antibiotic, usually after 48 to 72 hr. A recent review showed no difference in risk of renal damage at 6 months, between IV followed by oral therapy compared to IV therapy alone.¹¹ The duration of treatment for complicated UTI should be 10 to 14 days.^{2,3}

Oral Therapy

Children above 3 months of age who are accepting by mouth and not toxic (simple UTI) are treated with oral antibiotics for 7 to 10 days. Coamoxiclav, amoxicillin or cefixime may be used for initial treatment, and treatment modified after availability of sensitivity reports. Adolescents with cystitis may receive antibiotics for 3 to 5 days.¹

Supportive Care

It is important to maintain adequate hydration during the infection. Intravenous fluids may be required if the child appears sick, dehydrated or is unable to take orally. Routine alkalization of the urine is not necessary.

Assessing Response to Therapy

With adequate therapy, resolution of toxicity occurs within 24 to 48 hr and fever by 48 to 72 hr. Urine culture is sterile after 48 hr of appropriate antibiotics. However, a repeat urine culture is not required during or following treatment, unless symptoms fail to resolve despite 72 hr of adequate antibiotic therapy; symptoms recur, suggesting recurrent UTI; or contamination of the initial urine culture is suspected.

Antibiotic Prophylaxis

After a course of antimicrobial therapy, long-term low dose antibiotic prophylaxis is administered to patients

with (i) UTI below 1 year of age, while awaiting imaging studies, (ii) VUR, and (iii) frequent febrile UTI (3 or more episodes in a year) even if the urinary tract is normal.³ The medication is given as a single bedtime dose (Table 2). The antibiotic used should be effective, non-toxic with few side effects and not alter the bacterial flora or induce bacterial resistance. Agents that can be used include cotrimoxazole and nitrofurantoin. Cephalexin or cefadroxil is preferred in infants and those with deficiency of glucose-6-phosphate-dehydrogenase. Antibiotic prophylaxis is not advised in patients with urinary tract obstruction (e.g. posterior urethral valves), urolithiasis and neurogenic bladder, and in patients on clean intermittent catheterization.

Breakthrough UTI results either from poor compliance or associated voiding dysfunction. The UTI should be treated with appropriate antibiotics. A change of the medication being used for prophylaxis is usually not necessary. There is no role for cyclic therapy, where the antibiotic used for prophylaxis is changed every 6 to 8 weeks.

Evaluation After the First Episode of UTI

Imaging studies aim to identify urologic anomalies that predispose to pyelonephritis and detect evidence of renal scarring. The investigations are performed judiciously (Table 3), with minimum risks of radiation exposure and other complications.³

Choice of Modalities

Chiefly, combinations of three modalities may be required for evaluation. Renal ultrasonography provides information on kidney size and location, hydronephrosis, urinary bladder anomalies and post-void residual urine. An ultrasound may be performed even during therapy of the UTI. Operator dependence and poor sensitivity for detection of VUR limit its role. Radiocontrast micturating cystourethrogram (MCU) is necessary for diagnosing and grading the severity of VUR (Fig. 1) and defining urethral and bladder anatomy. The MCU is done within 2 to 3 weeks of treatment. Dimercaptosuccinic acid (DMSA) scintigraphy is a sensitive test for detecting renal scars, characterized by decreased uptake with loss of renal contours or presence of cortical thinning with decreased volume (Fig. 2). While DMSA is a sensitive test for detecting acute pyelonephritis,

Table 1: Antimicrobials for treatment of UTI

Medication	Dose, mg/kg/day
Parenteral	
Ceftriaxone	75-100, in 1-2 divided doses IV
Cefotaxime	100-150, in 2-3 divided doses IV
Amikacin	10-15, single dose IV or IM
Gentamicin	5-6, single dose IV or IM
Coamoxiclav	30-35 of amoxicillin, in 2 divided doses IV
Oral	
Cefixime	8-10, in 2 divided doses
Coamoxiclav	30-35 of amoxicillin, in 2 divided doses
Ciprofloxacin	10-20, in 2 divided doses
Ofloxacin	15-20, in 2 divided doses
Cephalexin	50-70, in 2-3 divided doses

Table 2: Antimicrobials for prophylaxis of urinary tract infections

Medication	Dose, mg/kg/day	Remarks
Cotrimoxazole	1-2 of trimethoprim	Avoid in infants <3 months old, glucose-6-phosphate dehydrogenase (G6PD) deficiency
Nitrofurantoin	1-2	May cause vomiting and nausea; avoid in infants <3 months old, G6PD deficiency, renal insufficiency
Cephalexin	10	Drug of choice in first 3-6 months of life
Cefadroxil	5	An alternative agent in early infancy

Usually given as single bedtime dose

Table 3: Evaluation following the first episode of urinary tract infection

Age	Evaluation*
Below 1 year	Ultrasound
	Micturating cystourethrogram (MCU)
	Dimercaptosuccinic acid (DMSA) renal scan
1-5 year	Ultrasound
	DMSA scan
	MCU, if ultrasound or DMSA scan is abnormal
Above 5 year	Ultrasound
	If ultrasound abnormal: MCU & DMSA scan

*Patients with recurrent UTI need detailed evaluation with ultrasonography, DMSA scan and MCU

Fig. 1: Grading of vesicoureteric reflux (VUR) on micturating cystourethrogram. Grade I: VUR does not reach the renal pelvis; Grade II: VUR extending up to the renal pelvis without dilatation of pelvis or calyceal fornices; Grade III: VUR extending up to the kidney, with mild dilatation or tortuosity of the ureter and renal pelvis, with no or minor blunting of the calyceal fornices; Grade IV: Moderate dilatation or tortuosity of the ureter, renal pelvis and fornices, with complete obliteration of the sharp angles of the calyceal fornices, but normal appearance of the papillary impressions; Grade V: Gross dilatation and tortuosity of the ureter, renal pelvis and calyces, with loss of papillary impressions on calyces

its diagnosis does not change management; routine use of DMSA scintigraphy in acute UTI is thus not justified. In order to detect renal scarring DMSA scan is recommended 3-months after therapy for UTI.

Direct radionuclide cystography (DRCG) is useful for follow up studies since its sensitivity for detecting VUR is high and involves less radiocontrast exposure. Drawbacks include poor anatomical resolution, lack of urethral visualization and inability to precisely grade VUR.

Recommendations for Evaluation

Recommendations for imaging following the first UTI are variable. All patients are screened with the aim to identify patients at high risk of renal damage, chiefly those below 1 year of age, and those with VUR or urinary tract obstruction. A 'high-risk' approach should be followed to avoid subjecting children with no abnormality to multiple

Fig 2: 99 mTc-DMSA scintigraphy showing multiple scars and loss of volume in the right kidney. The left kidney is normal

investigations. However, this approach is now tempered with the knowledge that intensive imaging and subsequent management do not significantly alter the long-term outcome of children with reflux nephropathy diagnosed following a UTI. In addition, the routine use of antenatal screening leads to a majority of the significant anomalies to be detected and managed after birth.

The Expert Group of the Indian Society of Pediatric Nephrology reviewed the current literature, keeping in view that in our country the diagnosis of UTI is often missed or delayed, and there are limitations of infrastructure and scarcity of resources for routine antenatal screening. Their recommendations on evaluation following the first UTI are summarized in Table 3.³ Briefly, all infants (<1 year) need to be evaluated aggressively using ultrasonography, MCU and DMSA scan. The early detection of scarring, high grade VUR or obstructive uropathy is likely to enable interventions that prevent progressive kidney damage. Since infants are at the highest risk, it is necessary that this group undergo focused evaluation. DMSA scintigraphy and ultrasound are required between 1 to 5 years, and ultrasound above 5 years of age. Further imaging with MCU is necessary if scintigraphy or ultrasound examination is abnormal. A milder grade of reflux, which may be missed by this approach, is not likely to contribute to renal scarring.

The above recommendations are based on the assumption that early detection of urologic abnormalities shall result in improved outcomes. It is possible that application of antenatal ultrasonography and availability of non invasive

methods for evaluating the lower tract might result in modification of the existing recommendations in future.

Asymptomatic Bacteriuria (ABU)

ABU refers to significant bacteriuria in a child who has no symptoms of UTI.¹ The frequency of ABU is about 1 to 2 percent in girls and 0.05 to 0.2 percent in boys. The organisms isolated in most cases are usually *E. coli* of low virulence. The condition is benign, does not cause renal injury and remits spontaneously with time. On the other hand, eradication of these non-pathogenic organisms may be followed by symptomatic infection with more virulent strains. Use of antibiotics to treat asymptomatic bacteriuria or antibiotic prophylaxis is not indicated. The presence of asymptomatic bacteriuria in a patient previously treated for UTI should not be considered as recurrent UTI.¹

Recurrent UTI

Recurrent UTI are observed in 30 to 50 percent children; most recurrences occur within 3 months of the initial episode. Predisposing factors include:

- Female sex
- Age <6 months
- Obstructive uropathy
- Severe (grade III-V) VUR
- Repeated pyelonephritis
- Voiding dysfunction
- Constipation
- Repeated catheterization.

Evaluation

Patients with recurrent UTI at any age should undergo detailed imaging with ultrasonography, MCU and DMSA scintigraphy.³

Prevention

Interventions that have been associated with a decrease in incidence of UTI include relief of constipation and voiding dysfunction.^{1-3,5} Adequate fluid intake and frequent voiding is advised. Antibacterial prophylaxis is indicated in children with recurrences, even in the absence of VUR.

Circumcision

Increased periurethral bacterial colonization in the uncircumcised may be a risk factor for UTI. Circumcision reduces the risk of recurrent UTI in infant boys, and might have benefits in patients with high grade VUR.^{12,13}

Voiding Dysfunction and Bowel Bladder Dysfunction

Voiding dysfunction refers to abnormal patterns of micturition in the presence of intact neuronal pathways without

congenital or anatomical abnormalities.¹⁴ When constipation is associated with a functional voiding disorder, the condition is referred to as bowel bladder dysfunction (BBD).^{3,14}

Children with recurrent UTI are likely to have dysfunctional voiding. A diagnosis of voiding dysfunction can be made based on history of the voiding pattern and urodynamic studies. A record of frequency and voided volume and fluid intake for two to three days is useful. The urinary stream should be observed, including for post void dribbling in boys. Voiding dysfunction should be suspected in children with (i) persistent high grade VUR; (ii) thickened urinary bladder wall >2 mm, (iii) post-void urine >20 ml, and (iv) spinning top configuration of bladder on MCU.³

The child is explained to follow a structured voiding pattern, with frequent voids and double micturition. Constipation is managed with dietary modification and medications. Patients with large post void residues, benefit from timely voiding, bladder retraining and clean intermittent catheterization. In patients with an overactive bladder therapy, with anticholinergic medications (*e.g.* oxybutinin) increases bladder capacity.

VESICoureteric Reflux

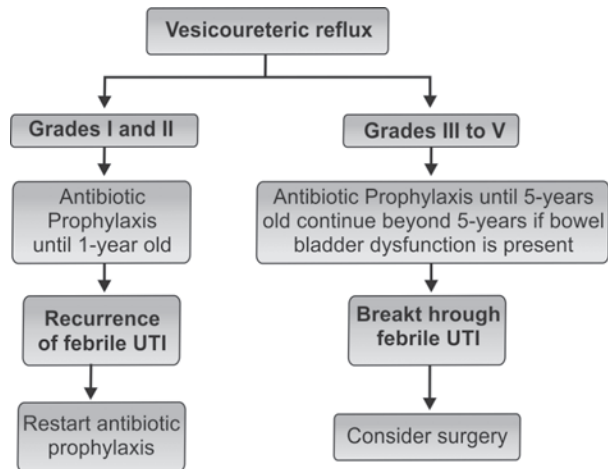

VUR refers to the retrograde flow of urine from bladder to ureters and pelvis at rest or during micturition.¹³ Its severity is graded using the International study classification from grade I to V, based on the appearance of the urinary tract on MCU (Fig. 1).¹⁵ Primary VUR tends to resolve by 6 to 10 year of age. Factors favoring resolution are younger age, and low grade and unilateral VUR. The rate of resolution is 70 to 90 percent for grades I-III and 10 to 35 percent for higher grades.³ Secondary VUR is due to bladder outflow obstruction, as with posterior urethral valves, neurogenic bladder or a functional voiding disorder.

Recognition of significant reflux is important since UTI in this setting predispose to renal parenchymal damage and renal scarring (reflux nephropathy), an important cause of hypertension and progressive renal injury. However, it is recognized that 10 to 20 percent male infants with severe VUR may have small kidneys without any history of UTI.¹⁶ Thus, not all children with reflux benefit from diagnosis or treatment.¹⁷

Therapy

Conventional therapies for VUR include antibiotic prophylaxis and surgical intervention.^{18,19} In patients with dilating reflux, the numbers of breakthrough UTI and risk of renal scarring were similar following surgical repair versus prophylaxis. Experts recommend that the management of patients with VUR should depend on the patient age, grade of reflux and whether there are any breakthrough infections.¹²

Flow chart 1: Management of vesicoureteric reflux. Medical therapy of VUR is based on the principle that VUR resolves over time, and prophylactic antibiotics maintain urine sterility and prevent infections while awaiting spontaneous resolution. Reflux takes longer to resolve if associated with bowel bladder dysfunction or if high grade reflux is present; such patients require prolonged prophylaxis. Surgical correction of VUR is indicated if breakthrough infections occur, since significant parenchymal injury may occur with pyelonephritis

Long term antibiotic prophylaxis is proposed to reduce periurethral colonization, reducing risks of recurrent UTI in patients. Antibiotic prophylaxis is discontinued once reflux subsides. As the risk of scarring decreases after 5 years in children with normal bowel and voiding habits, prophylaxis can be stopped even if VUR persists.²⁰

Surgery is reserved for patients with bilateral grade IV and V reflux persisting by 1 to 2 years of life, and those having breakthrough febrile UTI while on antibiotic prophylaxis, if parents prefer surgical intervention to prophylaxis, or in patients who show appearance of new scars and deterioration of renal function.^{19,20} An evaluation for voiding dysfunction should be done before surgery.

Flow chart 1 summarizes proposed guidelines for management of VUR.³ Patients should initially receive antibiotic prophylaxis while awaiting spontaneous resolution of VUR. Patients are followed closely for occurrence of breakthrough UTI. Repeat imaging is conducted after 18 to 36 months in those with grade III-V VUR, preferring radionuclide cystogram over MCU for follow-up evaluation. Evidence from few studies suggests that the strategy of prompt diagnosis and treatment of UTI might be as effective as antibiotic prophylaxis.^{1,21} Clinicians should however caution the parents regarding the risks of withholding antibiotic prophylaxis.

Dextranomer/hyaluronic acid copolymer (Deflux) endoscopic treatment has been used as an alternative to

surgical repair for patients with VUR.²² While the technique is less invasive and associated with satisfactory outcome, a significant proportion of patients, particularly those with bowel bladder dysfunction, may show persistence and/or recurrence of reflux and progressive renal damage.^{23,24} Endoscopic correction is currently not recommended as first line therapy.¹²

Screening of Siblings and Offspring

Reflux is inherited in an autosomal dominant manner with incomplete penetrance; one-third siblings and offspring of patients show VUR.²⁵ Ultrasonography is recommended to screen for the presence of reflux.

Follow-up

Patients with a renal scar (reflux nephropathy) are counseled regarding the need for early diagnosis and therapy of UTI and follow-up. Physical growth and blood pressure is monitored; investigations include urinalysis for proteinuria and estimation of blood creatinine. Annual ultrasound examinations are done to monitor renal growth.

Acute Kidney Injury in Children

Kanav Anand

INTRODUCTION

Incidence of acute kidney injury (AKI) in children appears to be increasing and the etiology has shifted from primary renal diseases to multifactorial causes. Children who have suffered from AKI due to any cause are at risk for development of kidney diseases several years after the initial insult. Derangement of renal functions is associated with increased morbidity and mortality.¹ The incidence of AKI in neonatal and pediatric units varies between 1 and 25 percent, depending upon the criteria used for its definition.^{2,3} Despite advances in therapy the mortality due to the condition is still high (30-40%) and a proportion of patients may progress to chronic kidney disease and dialysis dependency. AKI usually occurs in patients with previously normal renal functions, but may occasionally be superimposed on pre-existing renal disease (acute on chronic kidney disease). Derangements can vary from mild increase in the renal parameters to severe loss of organ function which requires supportive care in the form of renal replacement therapy. Initially everything was categorized under the term acute renal failure which generally represents the severe form of disease. Acute renal failure (ARF) is defined as a sudden loss of kidney function, occurring over a period of hours to days, manifested by accumulation of creatinine, urea and other metabolic waste products (azotemia) and often accompanied by reduction in urine volume (oliguria) with associated salt and water retention whereas, the diagnostic criteria for AKI include an abrupt (within 48 hours) reduction in kidney function, defined as 50 percent or greater increase in serum creatinine or oliguria (<0.5 ml/kg/hr) for more than 6 hours.

In 2002, the acute dialysis quality initiative group proposed the RIFLE criteria as interim consensus criteria for the definition and staging of AKI (Table 1).⁴ The acronym RIFLE defines three grades of increasing severity of acute renal dysfunction (risk, injury, and failure; R, I and

F, respectively) on the basis of graded changes in serum creatinine or urine output and two outcome variables (loss and end-stage kidney disease; L and E, respectively) based on the duration of loss of kidney function.⁵ Risk, injury, and failure are defined as increases in serum creatinine levels by 50 percent, 100 percent, or 200 percent respectively, or oliguria for 6, 12 or 24 hours, respectively. Another classification has been proposed by AKIN (Acute kidney injury network) which divides AKI into three stages (Table 1).^{6,7}

ETIOLOGY

There are many causes of AKI and the more common ones are listed in (Table 2). Some causes of AKI, such as rapidly progressive glomerulonephritis (RPGN), may present as AKI but rapidly evolve into chronic kidney disease (CKD). Several renal diseases, such as the hemolytic-uremic syndrome (HUS), Henoch-Schönlein purpura, and obstructive uropathy, may present as AKI. There may be improvement in renal functions to normal or near-normal levels or they may slowly deteriorate, leading to CKD, several months to years later. Children with AKI due to hypoxic/ischemic insults, HUS, acute glomerulonephritis and other causes are more likely to demonstrate oliguria or anuria. Neonates and children with acute interstitial nephritis, nephrotoxic renal insults including aminoglycoside nephrotoxicity and contrast nephropathy are more likely to have AKI with normal urine output, termed as nonoliguric AKI. In neonates, the common causes of AKI are birth asphyxia, sepsis, structural abnormalities of urinary tract (obstructive uropathy), drug toxicity and bilateral renal artery thrombosis secondary to umbilical artery catheterization.² The morbidity and mortality rates of nonoliguric AKI are less than those of oliguric AKI.⁸ Classification of acute kidney injury is shown in (Flow chart 1).

Table 1: RIFLE* and acute kidney injury network (AKIN) staging criteria for acute kidney injury

<i>RIFLE stage</i>	<i>AKIN stage</i>	<i>Serum creatinine criteria</i>	<i>Urine output criteria</i>
Risk	1	Increase in serum creatinine of 1.5- to two-fold from baseline (RIFLE and AKIN) or increase in serum creatinine of ≥ 0.3 mg/dl (AKIN)	< 0.5 ml/kg/h for 6 hours
Injury	2	Increase in serum creatinine of two- to threefold from baseline	< 0.5 ml/kg/h for 12 hours
Failure	3	Increase in serum creatinine of more than threefold from baseline or a serum creatinine of > 4 mg/dl with an acute rise of ≥ 0.5 mg/dl	< 0.5 ml/kg/h for 24 hours or anuria for 12 hours
Loss	Persistent renal failure for > 4 weeks		
End-stage renal disease	Persistent renal failure for > 3 months		

* RIFLE defines three grades of increasing severity of acute renal dysfunction (risk, injury, and failure: Respectively R, I, and F) on the basis of graded changes in serum creatinine or urine output and two outcomes variables (loss and end-stage kidney disease, L and E, respectively) based on the duration of loss of kidney function.

Table 2: Categories of acute renal failure in children

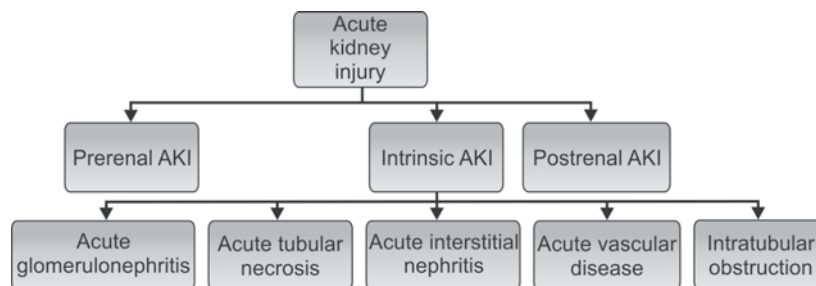

<i>Prerenal</i>	<i>Intrinsic Renal</i>	<i>Postrenal</i>
Intravascular volume depletion Dehydration Gastroenteritis Hemorrhage Diabetes Insipidus Burns Diuretics	Acute tubular necrosis (ATN) Ischemic Injury Prerenal causes Exogenous toxins Nephrotoxic antibiotics Chemotherapeutic agents NSAIDs ACE inhibitors and ARBs Radiographic contrast Venoms Heavy metals Ethylene glycol Endogenous toxins Myoglobinuria/ hemoglobinuria Tumor lysis syndrome	Posterior urethral valves Obstruction of a solitary kidney Bilateral ureteral obstruction Neurogenic bladder Trauma
Redistribution of fluid/vasodilatation Sepsis Pancreatitis Intestinal obstruction Peritonitis Nephrotic syndrome Hepatic failure	Acute interstitial nephritis Drug-induced or idiopathic Acute glomerulonephritis Postinfectious (Streptococcal) HSP, SLE, Goodpasture syndrome Vascular Pathology Renal artery/vein thrombosis HUS/TTP Cortical necrosis Congenital Renal dysplasia/hypoplasia Polycystic kidney disease	
Decreased Cardiac Output Congenital heart failure Cardiogenic shock Myocarditis Cardiac tamponade		

Prerenal Acute Kidney Injury

Prerenal AKI occurs due to renal hypoperfusion and renal functions recover on restoration of normal renal perfusion. There is an increase risk of intrinsic acute kidney

injury if renal hypoperfusion is sustained for long time.⁹ Hypovolemia and hypoperfusion leads to activation of sympathetic nervous system, renin angiotensin, aldosterone and antidiuretic hormone which helps to sustain

Flow chart 1: Classification of acute kidney injury

a near normal glomerular filtration rate (GFR) by maintaining intraglomerular capillary pressure and increasing proximal tubular sodium and water reabsorption. In prerenal AKI, GFR declines inspite of all these compensatory responses leading to excretion of concentrated urine which has low urinary sodium concentration (<20 mmol/L), a low fractional excretion of sodium ($<1\%$), a low fractional excretion of urea ($<35\%$) and high urine osmolality. Treatment of prerenal AKI is correction of underlying cause of renal hypoperfusion. In patients, who have true volume depletion, fluid resuscitation is the primary treatment. In patients with decreased effective arterial blood volume, treatment of primary organ failure will improve prerenal azotemia.

Intrinsic Acute Kidney Injury

Intrinsic AKI is divided into the following categories:

Acute Glomerulonephritis

Acute glomerulonephritis (GN) and rapidly progressive GN comprise a spectrum of glomerular diseases that present as AKI leading to progressive decline in renal function over days to weeks. Prompt recognition of these entities is critical because early initiation of therapy is essential to preserve kidney function and prevent irreversible renal damage. The prototypic form of acute GN is poststreptococcal GN. The presence of dysmorphic red blood cells and red blood cell casts on microscopic examination of the urinary sediment are pathognomonic for an acute glomerular process. Serologic studies including serum complement levels, markers for hepatitis B and C viruses, antistreptococcal antibodies, antinuclear antibodies, anti-neutrophil cytoplasmic antibodies and antiglomerular basement membrane antibodies may be helpful in making a diagnosis; however, renal biopsy usually is necessary for definitive diagnosis. The specific findings on kidney biopsy depend on the underlying glomerular process; proliferative lesions in the glomerulus, often associated with crescentic changes, are characteristic.

Acute Tubular Necrosis

Acute tubular necrosis (ATN) is the most common cause of intrinsic AKI. Most commonly ATN is precipitated by ischemic or nephrotoxic processes. Acute illnesses, sepsis, hypotension and nephrotoxic medications are contributing factors for its development. The clinical course of ATN can be highly variable. Initially there is an oliguric phase, beginning within 24 hours of the inciting event and it lasts for 1 to 3 weeks, followed by a diuretic phase, characterized by a progressive increase in urine volume, which usually is an indicator of renal recovery. Many patients, however, may be nonoliguric throughout their course. Mortality associated with ATN is high, with reported mortality rates as high as 50 percent to 70 percent in some series.¹⁰ Multiple studies have suggested that ATN is an independent risk factor for mortality.^{11,12} Majority of surviving patients recover their renal functions, although complete recovery may not occur.

The urinary sediment in ATN demonstrates many tubular epithelial cells and coarse granular casts, often described as 'muddy brown casts'. Tubular sodium reabsorption is impaired. The urinary sodium is greater than 40 mmol/L with a fractional excretion of sodium being >1 percent.

Ischemic acute tubular necrosis: When the hypoperfusion is more intense or prolonged, tubular cell injury ensues and renal dysfunction persists even after the hemodynamic insult resolves.¹³ As the name implies, the most evident site of injury following renal ischemia is the tubular epithelial cells, with evidence of both epithelial cell death (necrosis) and apoptosis.¹³

Nephrotoxic acute tubular necrosis: Nephrotoxic ATN may result from either endogenous or exogenous toxins. The endogenous heme pigments from hemoglobin and myoglobin cause ATN in the settings of massive intravascular hemolysis or rhabdomyolysis, respectively. Most cases of exogenous nephrotoxic ATN are associated with antimicrobial agents such as aminoglycosides and amphotericin B,

radio contrast media, chemotherapeutic agents including cisplatin and ifosfamide and acetaminophen.

Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) is associated with arthralgia and classic triad of fever, rash and eosinophilia, but this triad may be seen in only 10 to 30 percent of patients.¹⁴ Antibiotics and nonsteroidal anti-inflammatory drugs (NSAIDs) currently are the most common causative agents, although AIN can occur with almost any medication. The urinary findings in AIN include sterile pyuria, white blood cell casts, non-nephrotic range proteinuria, hematuria and eosinophiluria. The gold standard for diagnosis of AIN is renal biopsy.

Acute Vascular Syndromes

Acute vascular syndromes are divided into large-vessel and small-vessel disease. The large-vessel diseases include renal thromboembolism, renal artery dissection and renal vein thrombosis. The common feature of the large-vessel vascular syndromes is renal infarction, usually presenting with flank pain, hematuria and elevated levels of serum lactate dehydrogenase. Unilateral disease will not cause AKI unless it involves a solitary functional kidney. Diagnosis is made by using contrast-enhanced CT scan, radioisotope renography or angiography. Thrombolytic therapy or revascularization is usually not feasible; treatment usually consists of anticoagulation and supportive care.

More common than large-vessel disease is small-vessel disease resulting from atheroembolization or formation of fibrin thrombi into the distal renal vasculature. It is most common after surgical or angiographic manipulation of the aorta, often with a delayed onset of several days to weeks. The diagnosis is made most readily when cutaneous manifestations, including livedo reticularis and digital ischemia are present.

Intratubular Obstruction

Intratubular obstruction from precipitation of either proteins or crystals within the tubular lumen can also cause AKI. It can occur in setting of multiple myeloma, ethylene glycol ingestion and tumor lysis syndrome. In the tumor lysis syndrome, marked hyperuricemia leads to intratubular precipitation of uric acid crystals. Intratubular precipitation of acyclovir, indinavir and methotrexate is the major mechanism of AKI associated with the use of these drugs.

Postrenal Acute Kidney Injury

Postrenal AKI results from obstruction of the urinary collecting system. Obstruction may occur at the level of the bladder or urethra (lower tract obstruction) or at the level of the ureters or renal pelvis (upper tract obstruction)

bilaterally. Unilateral obstruction is usually not associated with a significant decrement in kidney function because of the preservation of function in the contralateral kidney. Common causes of obstruction in children include congenital ureteral strictures or posterior urethral valves. Postrenal AKI can present as a result of either complete or partial obstruction. Complete obstruction usually is associated with anuria, whereas partial obstruction may be asymptomatic or manifest with symptoms of voiding dysfunction such as frequency, hesitancy, intermittency, nocturia and incomplete emptying. Lower tract obstruction usually is diagnosed based on the presence of urinary retention. An elevated postvoid residual bladder volume can be measured by ultrasound or by measuring urine volume after placement of a bladder catheter. Combined plain film radiographs, ultrasonography, and high-resolution CT scans of the abdomen and pelvis are diagnostic in more than 90 percent of cases.¹⁵ Isotopic renography may be useful as a functional test to differentiate obstructive from nonobstructive urinary tract dilatation.

Clinical Evaluation of the Patient with Acute Kidney Injury

The clinical evaluation of the patient who has AKI begins with assessing whether the patient has prerenal, postrenal or intrinsic disease. Postrenal or obstructive disease is suggested by clinical symptoms of voiding dysfunction. Bladder outlet obstruction should be assessed clinically by asking for the urinary stream and radiologically by measuring postvoid residual bladder volume using an ultrasound. Upper tract obstruction should be assessed using renal ultrasound or CT scan.

Prerenal azotemia manifests as signs of intravascular volume depletion in the form of hypotension, orthostatic hypotension, tachycardia, flat neck veins, poor skin turgor and dry oral mucosa. The urinary sediment usually is without casts or cellular elements and the urine is usually concentrated (specific gravity >1.015; urine osmolality >350 mOsm/kg) with a low urine sodium concentration (<20 mmol/L). The fractional excretion of sodium, calculated as the ratio of urine (UNa) to plasma sodium concentration (PNa) divided by the ratio of urine (UCr) to plasma creatinine (PCr) expressed as percentage $\rightarrow ((\text{UNa}/\text{PNa})/(\text{UCr}/\text{PCr})) \times 100$ on a random urine sample and is usually less than 1 percent (Table 3). In patients, who have heart failure or liver disease, concomitant use of diuretics decreases the utility of urinary diagnostic indices. In patients, who have prerenal azotemia, the fractional excretion of urea is usually less than 35 percent, compared with normal values of more than 60 percent.¹⁶

The ultimate determination of whether a patient has prerenal or intrinsic AKI may require a diagnostic trial of

intravenous fluids. The differentiation between the causes of intrinsic AKI requires a careful clinical history and physical examination.

Some investigations which can aid in identifying the cause and complications of AKI are listed in Table 4. Urine microscopy may also provide useful clues to the diagnosis (Table 5). The presence of dysmorphic red blood cells and red blood cell casts are strongly suggestive of an acute glomerular process. The presence of white blood cells, white blood cell casts and eosinophiluria suggests the diagnosis of AIN. Tubular epithelial cells and muddy brown granular casts suggest ATN. Heavy oxalate, uric acid crystalluria or the presence of drug crystals suggests intratubular crystal deposition, whereas, the presence of nonalbumin proteinuria suggests a diagnosis of myeloma kidney. When the diagnosis remains uncertain, especially if there is suspicion of acute GN or AIN, a kidney biopsy may be indicated. The indications of renal biopsy in acute kidney injury have been mentioned in (Table 6).

Table 3: Dehydration/reduced renal perfusion (prerenal) vs. acute tubular necrosis (intrinsic renal)

	<i>Prerenal</i>		<i>Intrinsic renal</i>	
	<i>Child</i>	<i>Neonate</i>	<i>Child</i>	<i>Neonate</i>
UNa (mEq/L)	<20	<20	>40	>40
FeNa (%)	<1	<2	>1	>3
U _{osm} (mOsm/kg)	>500	>400	<300	<300
U _{osm} /P _{osm}	>1.5	>2	<0.8-1.2	<1
BU/creat	> 20:1	> 20:1	< 20:1	< 20:1
Fluid push	Urine↑	Urine↑	No response	No response

FeNa → fractional excretion of sodium = ((urine sodium × serum creatinine)/(serum sodium × urine creatinine)) × 100%;
 UNa → urinary sodium; U_{osm} → urinary osmolality; P_{osm} → plasma osmolality, BU → blood urea; creat → serum creatinine

AKI may occasionally be superimposed on chronic kidney disease. Features such as failure to thrive and growth retardation, hypocalcemia, hyperphosphatemia, hypertensive retinopathy, renal osteodystrophy and small contracted kidneys indicate an underlying chronic kidney disease. Urinary tract infection, use of nephrotoxic drugs, rapid increase in blood pressure and hypovolemia may precipitate AKI in such cases.

A high serum creatinine level, a reliable marker for AKI, signifies that the damage has already occurred as the serum creatinine rises only when about 50 percent loss of renal function has occurred.¹⁷ In order to pick up an early AKI so as to prevent the progression, nowadays a few novel biomarkers are being used such as serum cystatin C, urinary kidney injury molecule 1 (KIM-1), serum and urinary neutrophil gelatinase associated lipocalin (NGAL) and urinary interleukin 18 (IL-18).¹⁸ NGAL and KIM are specific for hypoxic and nephrotoxin mediated renal injury, whereas IL-18 is specific for hypoxic and ischemic renal damage.¹⁷ These markers help in early detection of AKI, approximately 1 to 2 days prior to the rise in serum creatinine values. Commercial kits for these biomarkers will be very soon available in the market.

MANAGEMENT

Fluid Management

Many children would require a fluid bolus to differentiate prerenal from intrinsic renal failure. One or more fluid challenges of 20 ml/kg of isotonic solution (0.9% normal saline or ringer's lactate) over 30 to 60 minutes is used depending on the volume status of the child. Diuretics (furosemide 2-3 mg/kg IV) may be tried if the bolus has no effect. This should normally induce a diuresis over

Table 4: Investigations in patients with acute kidney injury

Blood	Complete blood counts Blood urea and creatinine Electrolytes (sodium, potassium, calcium, phosphate) Blood Gas (pH, bicarbonate)
Urine	Urinalysis Culture (if symptoms of urinary infection are present) Fractional excretion of sodium Osmolality
Radiology	Chest X-ray (for fluid overload, cardiomegaly) Ultrasonography (to identify any obstruction or dilatation) Renal doppler (for suspected arterial or venous thrombosis) Micturating cysto urethrography (if suspecting urethral obstruction) DTPA (to rule out obstructive uropathy)
ECG (for hyperkalemia)	
Investigations to establish the cause	Peripheral smear examination, platelet count, reticulocyte count, blood LDH levels, stool culture (in suspected D+ hemolytic uremic syndrome) Blood ASO, serum C3 levels, antinuclear antibodies (ANA), antineutrophil cytoplasmic antibodies (ANCA) Renal Biopsy

Table 5: Urinalysis findings in acute renal failure

<i>Prerenal azotemia</i>	<i>Acute tubular necrosis</i>	<i>Cortical necrosis</i>	<i>Interstitial nephritis</i>	<i>Glomerulonephritis</i>	<i>Postrenal</i>
Increased specific gravity, normal urinalysis	Granular casts, epithelial cells, epithelial casts, pigmentation	Gross or microscopic hematuria, proteinuria	Pyuria, WBC casts, eosinophiluria	Gross or microscopic hematuria, RBC casts, dysmorphic RBCs, proteinuria	Normal urinalysis

Table 6: Indications of renal biopsy in acute kidney injury

- Rapidly progressive glomerulonephritis
- AKI in transplanted kidney
- Unremitting AKI lasting for more than 4 weeks
- AKI in children on nephrotoxic drugs
- Prognostication in hemolytic uremic syndrome
- AKI of unknown etiology

next 2 to 3 hours if renal tubular function is intact.¹⁷ Fluid needs to be restricted in established oliguric/anuric renal failure. Total fluids should be restricted to 400 ml/m² of body surface area plus the urine output. Extra losses, e.g. from overhead warmers, gastrointestinal losses etc. needs to be replaced as well.

Electrolyte Management

Sodium levels are usually low in AKI because of fluid overload. Urinary sodium should be used as a marker for total body sodium. Sodium intake should be restricted to 2 to 3 mEq/kg body weight per day, together with fluid restriction, to prevent sodium and fluid retention with resultant hypertension. Symptomatic hyponatremia may need to be corrected with hypertonic saline.

Patients with oligoanuric AKI should not receive potassium or phosphorus unless they exhibit hypokalemia or hypophosphatemia. Hyperkalemia is common in AKI as the kidneys handle 90 percent of daily potassium excretion. Hyperkalemia needs to be treated aggressively as it can be life threatening.

Emergency management includes,

IV Calcium Gluconate 0.5 to 1 ml/kg

Salbutamol nebulisation 5 to 10 mg

IV Sodium bicarbonate 1 to 2 mEq/kg

Regular insulin 0.1 to 0.2 U/kg, with glucose (50%) 0.5 to 1 gm/kg.

Potassium binding resins 1 gm/kg/dose every 6 to 8 hourly.

Hyperphosphatemia is treated with the help of phosphate binders like calcium acetate, lanthanum carbonate, sevelamer which are given along with food so as to bind with the dietary phosphate.

Patients with AKI secondary to nephrotoxic medications or interstitial nephritis often demonstrate polyuria, placing them at risk for severe fluid and electrolyte losses.

In order to appropriately manage these patients, it is ideal to have a urinary catheter *in situ* and obtain weights and serum electrolyte levels at least once per day.

Nutrition

Adequate nutrition in critically ill children with AKI is a crucial component of their treatment, as they are at an increased risk of developing protein-energy malnutrition. Presence of renal replacement therapy (RRT) contributes to nutritional losses, especially amino acids and water-soluble vitamins.

The major goals of nutrition management are:

- Adequate calorie intake
- Protein intake of 2 to 3 gm/kg/day, with an adequate increase during renal replacement therapy to account for the losses
- Minimize potassium and phosphate intake
- Restrict fluid intake, which may mean increasing calorie density of feeds.

Treatment of the Underlying Disease

The basic pathological process which has caused the AKI should be targeted in order to prevent the ongoing renal injury. The strategy would include fluid resuscitation for intravascular fluid depletion which could have led to pre-renal AKI, treatment of sepsis with appropriate antibiotics, adequate cardiac support in conditions of decreased cardiac output, omission of nephrotoxic drugs, immunosuppression for lupus and Henoch Schonlein purpura nephritis, relieving the renal vessel occlusion and fulguration of posterior urethral valves.

Renal Correction of Drug Doses

Drug dosing must be altered for patients with AKI, not only for avoiding kidney injury, but also to avoid toxic accumulation of drugs and their metabolites which should be excreted by the kidney. When glomerular filtration rate falls to less than 50 percent of normal, most of the drugs excreted by the kidney will require modifications in scheduled dosing. This modification can be in terms of reduction of dosage or increasing the dosing interval. These drug dosages need to be further modified if the patient is on renal replacement therapy (RRT), depending on the clearance characteristics of the drug by the particular RRT modality.

Pharmacological Therapy

Inotropic agents are used for preservation of renal perfusion in critically ill patients unresponsive to volume repletion. At low or so called “renal doses” of dopamine (0.5–2 mcg/kg/min), there is an increase in renal plasma flow and sodium excretion but these effects are short-lived. A number of trials have seriously questioned the utility of “renal dose” dopamine in reversing oliguria and many centers have abandoned its use for this purpose.¹⁹

Dobutamine and norepinephrine have shown proven benefits in patients with AKI by increasing the cardiac output, leading to an increase in renal blood flow.

Vasopressin too has been effective in maintaining renal perfusion in patients with septic shock who were unresponsive to catecholamines. It increases the systemic vascular resistance by direct action on the vascular smooth muscle cells.

Renal Replacement Therapy

There are various modalities of RRT available to the pediatric intensivists today to support the renal system, giving it the much needed time to recover from any injury. The usual indications are:

Renal

- Oliguria (unresponsive to diuretics and/or fluid challenge)
- Anuria (nonobstructive)
- Severe Metabolic acidosis (pH <7.2, despite bicarbonate therapy)
- Severe or persistent Hyperkalemia ($K^+ >6.5$ mEq/L, $K^+ = 5.5$ -6.5 mEq/L with ECG changes)
- Azotemia

Uremic symptoms (encephalopathy, seizures, myopathy, pericarditis, bleeding)

Hyponatremia ($Na^+ <120$ -125 mEq/L, esp. if symptomatic)

Nonrenal

Fluid overload

Anticipated large transfusion in trauma or coagulopathy

Inborn errors of metabolism

Sepsis

Postcardiopulmonary bypass systemic inflammatory response syndrome

Pancreatitis

Drug overdose

The modalities available for RRT include peritoneal dialysis (PD), hemodialysis (HD), continuous renal replacement therapy (CRRT). CRRT can be arteriovenous or venovenous in nature, having 3 different subtypes, namely hemofiltration, hemodialysis and hemodiafiltration.

Solute removal is termed as “clearance” and fluid removal is called “ultrafiltration”. Clearance and ultrafiltration across a membrane (peritoneum in PD, filter membrane in HD and CRRT) forms the basis of renal replacement therapy. The effectiveness of any RRT is a measure of its effectiveness in ultrafiltration and clearance.

There are two mechanisms involved in the transfer of solutes across any semipermeable membrane: diffusion and convection. Diffusion is the movement of solute along its concentration gradient between the dialysate and blood. The “dragging” movement of solute with the moving stream of ultrafiltrate is known as convection or “solvent drag”.

Tables 7 and 8, give the comparison between the various modalities of renal replacement therapy.

Table 7: Comparison between the three techniques of renal replacement therapy

	PD	HDi	CRRT
<i>Method specificities</i>			
Vascular access (ECC)	No	Yes	Yes
Complex method with specific expertise	Low	Moderate	High
Systemic anticoagulation	No	Frequent	Frequent
<i>Dialysis dose</i>			
Efficacy to remove a toxin	Moderate	High	High
Efficacy to remove fluid	Moderate	Moderate	High
<i>Clinical situation indication</i>			
Hemodynamic instability	Yes	No	Yes
Intracranial hypertension	Yes	±	Yes
ARDS	±	Yes	Yes
Abdominal surgery	±	Yes	Yes

PD → peritoneal dialysis; HDi → intermittent hemodialysis; CRRT → continuous renal replacement therapy; ECC → extracorporeal circulation; ARDS → acute respiratory distress syndrome

Table 8: Renal replacement therapy

<i>RRT Modality</i>	<i>Advantages</i>	<i>Disadvantages</i>
Peritoneal dialysis	<ul style="list-style-type: none"> • Minimal equipment needs • Minimal training needs • Feasible in small infants • Minimum hemodynamic compromise • No systemic anticoagulation • More physiological due to its continuous nature • No need for vascular access 	<ul style="list-style-type: none"> • Slow and less efficient solute removal • Unreliable and variable ultrafiltration • Respiratory compromise – abdominal compartment syndrome • Peritonitis • Catheter obstruction, leakage
Hemodialysis	<ul style="list-style-type: none"> • Maximum solute clearance • Readily available • Short treatment time • Accurate ultrafiltrate 	<ul style="list-style-type: none"> • Hemodynamic instability • Rapid fluid and solute compartment shifts • Difficult to use in small infants • Complex equipment • Requires vascular access • Heparin anticoagulation
CRRT	<ul style="list-style-type: none"> • Continuous control of fluid status • Accurate ultrafiltrate • Well tolerated by hemodynamically unstable patients • Excellent solute clearance • More physiological • Able to pump in huge amounts of fluids in oligo-anuric patients • Smaller circuit volumes 	<ul style="list-style-type: none"> • Systemic anticoagulation (though regional anticoagulation may be used) • Frequent filter clogging • Hypotension in small infants • Cost • Requires expertise • Vascular access necessary

Outcomes

Despite all the advances in renal replacement therapies, the morbidity and mortality due to AKI remains high (30-50%).²⁰ The recovery and long-term outcome of the children with AKI depends upon the underlying condition, associated sepsis, multiorgan dysfunction and delay in onset of appropriate therapy.

Approach to Hematuria in Children

Amish Udani, N Prahlad, M Vijayakumar

Hematuria signifies blood in the urine and it can be macroscopic or microscopic. It can be true hematuria with RBC's in urine or can be red colored urine which is called pseudohematuria. Children with hematuria are brought to the notice of pediatric nephrologist often early in the disease course as it alarms the child, parents and the pediatrician. Normal children do excrete RBC's in urine with prevalence of 0.5 to 2.0 percent which can increase in the presence of fever or after exercise.¹ In nonlife-threatening situations when the cause of hematuria is not found on initial evaluation, these children are kept under regular follow-up with re-evaluation done as per need.

DEFINITION

Various definitions are available once we consider hematuria in children.² Understanding the concept of these definitions will help us towards the correct diagnosis and hence proper evaluation can be done based on the diagnosis.

Macroscopic hematuria: In this situation the hematuria is obvious. Parents bring the child with blood in the urine and dipstick and microscopic examination of urine is done to confirm the hematuria. Dipstick is positive for true hematuria, myoglobinuria and hemoglobinuria and negative in pseudohematuria due to rifampicin, colored food and beetroot while sediment examination shows RBC's and RBC casts in true hematuria.

Microscopic hematuria: Most of the times this is diagnosed on examination of urine only either for a symptom or for screening purposes. This indicates presence of abnormal number of RBCs in urine. More than 5 RBC/mm³ in uncentrifuged urine and more than 5 RBC/HPF in a centrifuged specimen (10 ml urine, 2000 rpm for 5 minutes) will denote significant hematuria.

Transient hematuria: This condition is usually microscopic and benign and seen in fever, infections, trauma and exercise. These children need repeat urine examination to see for persistence.

Persistent hematuria: This usually indicates a renal disease. Persistent presence of RBC's in 3 urine analysis obtained at least one week apart with or without other cellular deposits or recurrent macroscopic hematuria constitutes persistent hematuria.

Symptomatic hematuria: It always indicates underlying disease and needs a detailed evaluation. Usually it occurs in association with features like hypertension, edema and urinary symptoms.

Asymptomatic hematuria: It is usually microscopic but it can be macroscopic also. It may be the sole abnormality with neither history nor physical examination providing any indication of systemic, renal or urological disorders. These children should be kept on long-term follow-up to identify a benign or a slowly progressive disease process in them.

Isolated hematuria: Children belonging to this group can have both gross and microscopic hematuria. Persistent isolated hematuria with severe renal histological changes in a child is unusual. Persistent microhematuria interspersed with episodes of gross bleeding or with proteinuria signifies serious illness and it is mostly renal in origin. These children need long-term follow-up as hematuria can disappear, or the child can develop additional renal or systemic abnormalities, or rarely isolated hematuria can persist.

DETECTION OF HEMATURIA

Dipstick examination of urine can be used as a screening procedure but documentation of hematuria by microscopic examination is always mandatory. Dipsticks depends on peroxidase like chemical reaction between

free hemoglobin or hemoglobin present in intact RBC or myoglobin in urine and a chemical tetramethylbenzidine present in the strip producing a blue color. It is capable of detecting 3-10 RBC/μl of uncentrifuged urine. It has 100 percent sensitivity and 99 percent specificity. They are costly but good as screening test for hematuria.

Macroscopic hematuria is visible to the naked eye and can be associated with significant proteinuria or RBC casts. Presence of RBC's in urine should always be confirmed by microscopic examination of 10 to 15 ml of freshly collected sample centrifuged at 2000 rpm for 5 minutes, decanting the supernatant, then resuspending the sediment in remaining 0.5 ml.^{3,4} Microscopic hematuria seen in asymptomatic cases should be given importance in the presence of significant proteinuria.⁵

Absence of RBC on microscopic examination with positive dipstick test suggests hemoglobinuria or myoglobinuria which can be distinguished by spectrophotometry. Bedside test to identify hemoglobinuria is by centrifugation of urine wherein the supernatant fluid is uniformly pink whereas in true hematuria it is dirty brown.⁵ Dipsticks can be false positive in alkaline urine pH >9.0 or contamination with menstrual blood or fever or exercise or contamination with oxidizing agents and false-negative in the presence of formalin or ascorbic acid.¹

MECHANISM OF HEMATURIA

Blood in urine can have its origin either from the glomeruli or from renal tubules and interstitium. It can also originate from the urinary tract including the collecting systems, ureters, bladder and urethra. In glomerular hematuria the RBC's cross the glomerular endothelial-epithelial barrier and enters the capillary lumen through structural discontinuities in the capillary wall. These discontinuities seem to be at the capillary wall-mesangial cell reflections. One should note that the renal papillae are susceptible to necrotic injury from microthrombi and anoxia in children with a hemoglobinopathy like sickle cell disease or in those exposed to toxins. Episodes of transient microscopic or macroscopic hematuria during systemic infections or after moderate exercise are seen due to altered renal hemodynamic responses and may not signify a primary renal disease. Mechanical erosion of the mucosal surfaces in the urinary tract by the calculi or gravel can result in hematuria.⁶

CAUSES OF HEMATURIA

Various conditions causing hematuria are given in Table 1.² Common systemic conditions that can cause hematuria include disseminated intravascular coagulation (DIVC) and bleeding diathesis.² Glomerular diseases causing hematuria include postinfective glomerulonephritis (PIGN) which is the commonest followed by chronic glomerulonephritis like IgA glomerulonephritis (IgA GN)

Table 1: Causes of hematuria

Systemic disease

Disseminated intravascular coagulation (DIVC)
Anticoagulant therapy
Snake bite envenomation
Hemorrhagic disease
Thrombocytopenia

Glomerular disorders

Acute glomerulonephritis (ANS)
Chronic glomerulonephritis (membranous nephropathy, membranoproliferative GN)
IgA nephropathy
Systemic lupus erythematosus, hemolytic uremic syndrome, Henoch-Schönlein purpura
Renal vasculitis
Alport's syndrome
Benign familial hematuria
Renal vein thrombosis
Acute cortical necrosis

Nonglomerular disorders

Hypercalciuria
Hyperuricosuria
Hyperoxaluria
Renal stone disease
Cystitis (viral hemorrhagic, drug induced)
Genitourinary anomalies with infection
Tumors
Polycystic kidney disease
Trauma
Foreign body
Sickle cell hemoglobinopathy
Urinary tract infection

Conditions mimicking hematuria (pseudohematuria)

Foods containing beetroot
Drugs—furazolidone, pyridium, rifampicin
Pigmenturia—hemoglobinuria, myoglobinuria, bilirubinuria

and membranoproliferative glomerulonephritis (MPGN). Acute cystitis due to adenovirus, hypercalciuric conditions, renal stone disease and lastly tumors are common causes of nonglomerular hematuria.

FEATURES OF HEMATURIA

One should look into various presenting features and clinical examination findings to determine the source of bleeding as renal parenchymal (intrarenal) or from collecting system (extrarenal) of the kidneys.^{2,7} Some of the common presenting features of diseases causing hematuria are given in Table 2.²

Glomerular hematuria: Urine is usually tea colored and blood is seen throughout urinary stream and hence is termed total hematuria.⁷ Hematuria is usually painless and edema, hypertension and history of preceding or

Table 2: Presenting features of hematuria

<i>Etiological condition</i>	<i>Associated features</i>
<i>Glomerular</i>	
Acute postinfective GN	Edema, hypertension, oliguria, mild proteinuria
Membranoproliferative GN	Edema, proteinuria, hypertension
Henoch-Schönlein purpura	Purpura, arthralgia, abdominal symptoms
IgA nephropathy	Recurrent hematuria, synpharyngitic
Alport's syndrome	Ear, eye abnormalities, family history
Hemolytic uremic syndrome	Microangiopathic hemolytic anemia, renal insufficiency \pm dysentery
<i>Nonglomerular</i>	
Acute interstitial nephritis	Fever, rash, eosinophilia; history of drug intake
Urinary tract infection	Fever, flank pain, dysuria
Hypercalciuria, hyperuricosuria, hyperoxaluria	Colicky pain; family history of stones
Urolithiasis	Colicky pain, graveluria, family history
Hydronephrosis	Flank pain, abdominal mass
Wilms tumor	Abdominal mass
Hemorrhagic cystitis	Follows drug intake or viral infection with suprapubic pain or passage of clots
Coagulation disorder	Bleeding from other sites
Polycystic kidney	Abdominal mass, hypertension
AV malformations	Passage of clots, malformations elsewhere

associated infection are commonly seen. Family history of renal failure and deafness can be present. History of recurrent or persistent fever, arthralgia, arthritis, recurrent wheeze, recurrent jaundice and abdominal pain may be present pointing towards secondary glomerulonephritis. Presence of RBC casts in urine signifies glomerular hematuria and is associated with persistent or heavy proteinuria of 2+ or more or spot urine protein to creatinine ratio of >0.5 . The RBC's are dysmorphic by phase contrast microscopy and acanthocytes are common.² Blood clots and crystals are absent.

Nonglomerular hematuria: Urine is bright red. Dysuria and increased frequency are noted. Prolonged irregular fever of UTI can be seen. Features of renal stone disease like abdominal pain, vomiting and passage of gravel may be present. Absence of RBC casts and less than 15 percent dysmorphic RBCs in urine may signify nonglomerular hematuria.² Blood clots and crystals may be seen. Though proteinuria is seen it is not heavy and is less than 2+ or spot urine protein to creatinine ratio is <0.5 .

Exercise related hematuria: Rarely children following exercise can develop microscopic or macroscopic hematuria. Glomerular RBC and RBC casts were documented in few of them and otherwise urine analysis is normal at other times. Usually they are kept under surveillance.²

Benign familial hematuria: These children with hematuria will have first degree relative with hematuria without chronic kidney disease or sensorineural deafness. On the contrary children with Alport's syndrome of familial hematuria will have first degree relative with hematuria, chronic kidney disease and sensorineural deafness. Benign familial hematuria usually runs a nonprogressive course and end stage renal disease is very rarely reported.² Electron microscopy of kidney biopsy show thin glomerular basement membrane.

APPROACH TO HEMATURIA

A good history, physical examination and urine analysis helps to determine the type of hematuria (glomerular or nonglomerular) and the urgency of evaluation of the cause for hematuria.² Special stress should be given to family history of renal disease/deafness, identification of anatomic abnormalities and presence of macroscopic hematuria.

Family history is important in the evaluation of hematuria in children. Alport's syndrome should be doubted in a child when there is a first degree relative of the child with hematuria, sensorineural deafness and renal failure. Other diseases that carry a genetic origin include lupus nephritis, hemophilia and sickle cell disease. Nephrolithiasis and IgA GN also have a familial association. The thin glomerular basement membrane disease is a common cause of benign familial hematuria in children. Family members may not be aware that they have microscopic hematuria and should always be screened with a microscopic urinalysis.

Systemic diseases with thrombocytopenia or disseminated intravascular coagulation can present as hematuria. The use of furosemide for congenital heart disease can lead to hypercalciuria and subsequently, hematuria. Antibiotics and over-the-counter medications may cause interstitial nephritis. Chemotherapy (cyclophosphamide) and radiation for malignancies can explain isolated hematuria in children.

In the neonatal period, hematuria due to thrombosis of the renal vein or artery can occur especially after umbilical catheterization. Predisposing factors for renal vein thrombosis include perinatal asphyxia, dehydration, septicemia, shock, and coagulopathies secondary to protein C deficiency. Clinically, they present as gross hematuria with unilateral or bilateral renal mass. Renal ultrasonogram and Doppler studies of renal vessels help in the diagnosis.

Periorbital edema is frequently the first site of renal edema in children. Raised JVP, presence of gallop and

basal lung fields with crackles indicate fluid overload. Nephrotic edema may not have features of fluid overload as mentioned above. Costovertebral angle tenderness may indicate upper UTI. Recent trauma can be detected by findings of flank bruises and pain. Examining the abdomen for masses is critical for the identification of tumors, polycystic kidneys or hydronephrosis. Ascites usually suggests nephrotic syndrome. The examination of the skin can give evidence of pallor or rash. Pallor indicating anemia may signify either acute loss of blood as in hemolytic uremic syndrome or a chronic kidney disease. A fundoscopic examination of the retina, looking for evidence of long-standing hypertension or lenticonus as seen in Alport's syndrome, should be performed.

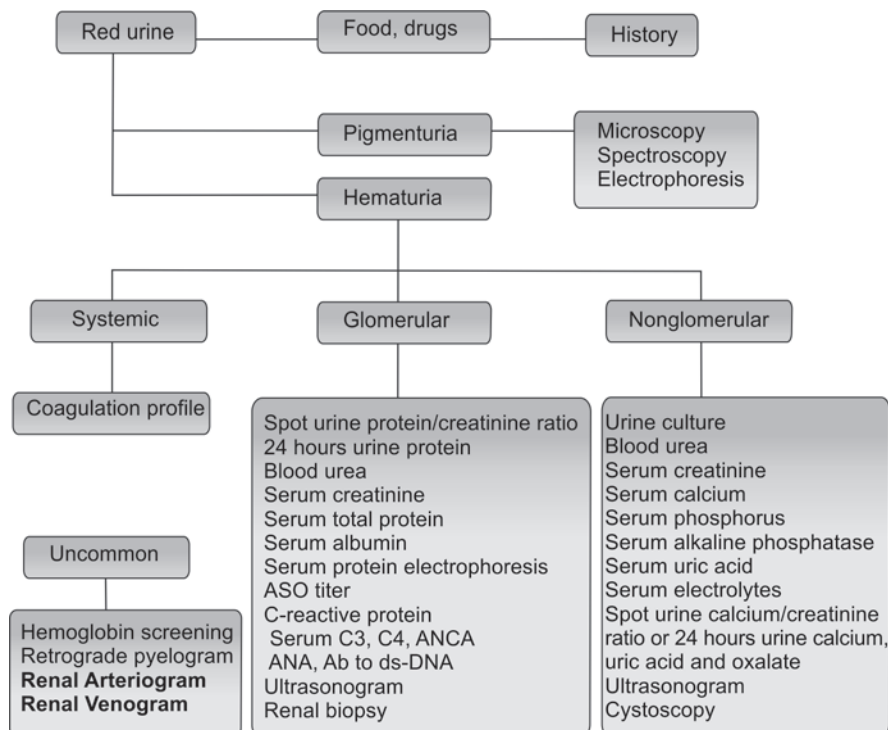

The presence of proteinuria and hematuria on urinalysis suggests glomerulonephritis. Proteinuria should not exceed 2+ if the only source of protein is from the blood.⁷ The presence of proteinuria, hypoalbuminemia and hypercholesterolemia suggest nephrotic syndrome. Pertinent to glomerulonephritis, laboratory investigations include a complete blood count, throat culture, ASO titer and serum estimation of C3, C4 levels, albumin, creatinine and electrolytes. The complement C3 level is low in acute poststreptococcal glomerulonephritis, subset of MPGN, and lupus nephritis. Microscopic hematuria almost always warrants referral to a pediatric nephrologist. Indications for renal biopsy in them include persistent microscopic hematuria for more than 1

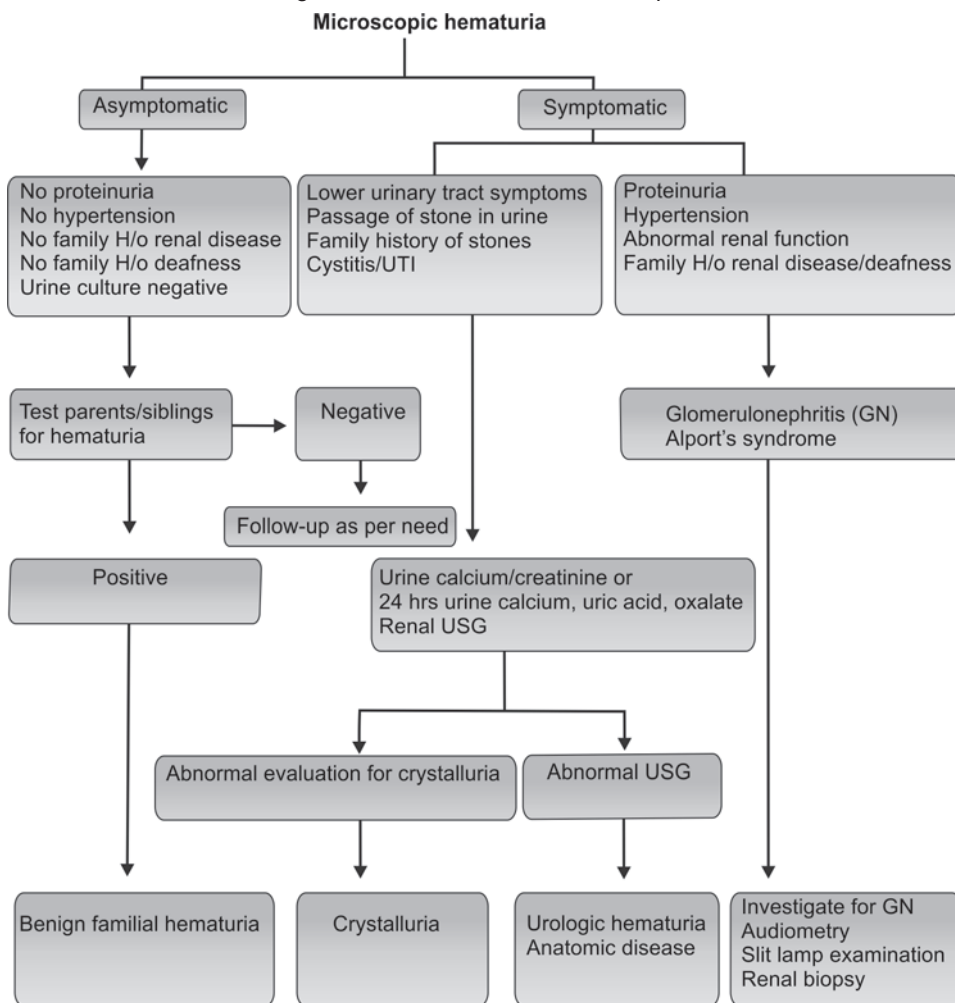

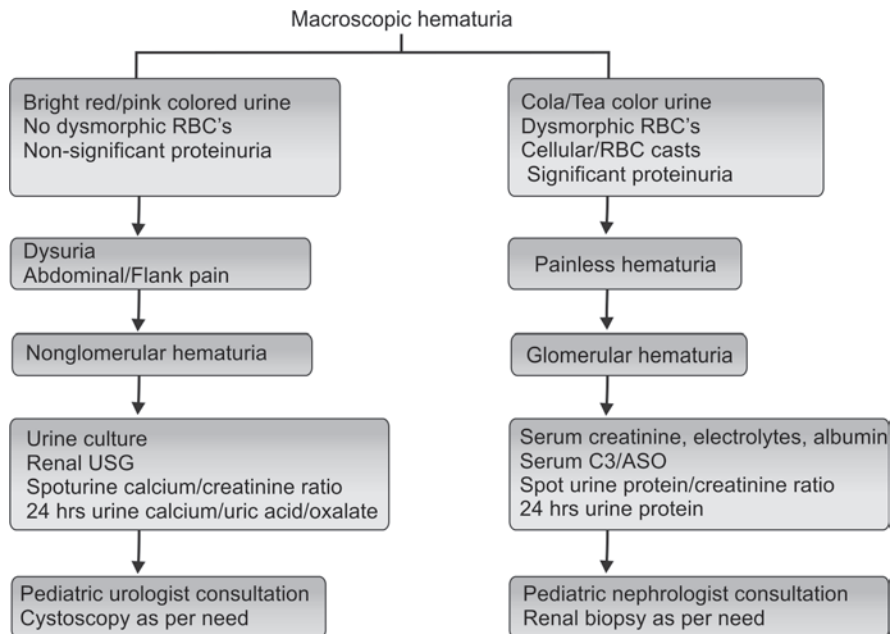

year and recurrent gross hematuria with decreased renal function, proteinuria or hypertension.⁸

In crystalluria or renal stone disease, the initial work up consists of ultrasonogram and screening the urine for calcium excretion by Ca/Cr ratio or estimation of 24-hour urine calcium, uric acid, oxalate and citrate excretion, serum creatinine, electrolytes, uric acid, calcium and albumin levels. There have been reports of recurrent abdominal and flank pain in children with idiopathic hypercalciuria. In addition, noncalculous idiopathic hypercalciuria is an important contributing factor to recurrent UTI in children. If the kidney-ureter-bladder is negative for stones, abdominal and pelvic spiral computed tomography scan should be obtained in children with a clinical picture of renal stone disease. A nephrology/urology consultation is appropriate if a stone is detected. Rare causes include tumors and some anatomic or vascular problems.⁵ Arteriovenous malformation of the kidney can present with gross hematuria. Renal ultrasonogram and CT scan of the abdomen may locate the tumor or malformation. Renal angiography offers a definitive diagnosis. Most of the conditions requiring advanced work up should be referred to a pediatric nephrologist or urologist.

A simple practical approach towards laboratory evaluation is given in Flow chart 1.² Algorithmic approach to microscopic and macroscopic hematuria is given in Flow chart 2 and 3.⁹

Flow chart 1: Laboratory evaluation of hematuria

Flow chart 2: Algorithm for evaluation of microscopic hematuria**Flow chart 3:** Algorithm for evaluation of macroscopic hematuria

CONCLUSION

Hematuria in children is usually a frightening symptom not only for the child but also for the doctor attending on the child. A good detailed history and adequate clinical examination will direct us towards the cause of hematuria. Algorithmic approach of evaluation will help us to come to your conclusion on the etiology. Once the diagnosis is made the treatment is essentially based on it. If no diagnosis is made initially with the available clinical picture and evaluation it is always better to keep the child under surveillance as at a later date the presentation may direct us towards the correct diagnosis. If we follow the simple approach that usually macroscopic hematuria has a pathological background and microscopic hematuria in a significant number of children can be benign and needs only a follow-up, we can face the symptom with ease. Once again remember that not in all children of hematuria can a diagnosis be arrived at initially. Please note that the two important nonpostinfective causes of hematuria are IgA GN and hypercalciuric syndromes. Early detection and appropriate timely interventions delay the progression to end stage renal disease in them. Proper importance should be given to meticulous follow-up.

Systemic Arterial Hypertension in Children and Adolescents

S Srinivasan

Systemic arterial hypertension (SAH) in children and adolescents is one of the increasingly observed and investigated clinical entities in the last two decades. Specific guidelines from various nations around the globe regarding its definition, recognition, causal identification with investigative work up, treatment and preventive modalities are brought about to facilitate the treating pediatricians.¹⁻⁷ Universally among pediatricians there is a heightened awareness of the increasing incidence of hypertension in children and adolescents, more so in obese children. They are also keen to know the emerging data on pediatric hypertension with regard to the possibility of early and progressive hypertensive target organ damage in those with untreated or poorly controlled hypertension and the potential preventive role they have to play in reducing the emerging burden of early hypertension related cardiovascular and renal morbidities.

The objectives of a rational clinical approach to SAH in children and adolescents are:

1. To ensure without an element of doubt its presence by accurate and repeated measurements using reliable BP apparatus and appropriate cuff size and approved and available regional or national BP centile charts (from neonatal period to completion of adolescence) for males and females.
2. To recognize hypertensive urgencies/emergencies and institute prompt, effective and safe treatment.
3. To identify its nature—Acute/chronic; transient/sustained (persistent)/paroxysmal; systolic/diastolic/both.
4. To identify presence of risk factors for hypertension by clinical history and examination.
5. To identify presence of clinical pointers or markers for identifiable causes of secondary hypertension.
6. To identify without undue delay the specific cause of secondary hypertension by institution of rational, cost

—effective, meaningful and stepwise/staged investigative plan.

7. To institute appropriate and effective therapeutic modalities to treat and remove the cause of secondary hypertension.
8. To evaluate and recognize the absence or presence of any early target organ damage so as to prevent, reverse or minimize this effect.
9. To incorporate educational inputs to affected children and family members to ensure compliance and adherence to management strategies.
10. To monitor the immediate and long-term therapeutic response, adverse effects of drugs, compliance and markers of target organ response.

Epidemiological Considerations⁸⁻¹¹

Recommendations of the task force on hypertension in children and adolescents in US gave impetus to many epidemiological and screening studies in childhood populations of various ethnic groups in that nation. They give enough evidence to indicate a perceptible trend of increasing incidence of hypertension in these age groups. While mid 1970 studies reported an incidence of 1 to 2 percent in healthy, school attending children, studies in this decade report an incidence of 3 to 5 percent. Recent survey in USA has reported a prevalence of prehypertension in children to be 10 percent and hypertension to be around 4 percent. Another important aspect of childhood hypertension in USA is the recent revelation from 4 studies that the levels of both systolic and diastolic BP are slowly rising in a few ethnic American boys and girls over the years.

Pathogenesis and Pathophysiology of Hypertension in Children and Adolescents¹²⁻²²

In majority of neonates, infants and children with hypertension, hypertension is secondary to an underlying renal,

renovascular, cardiovascular, endocrinal, postinfective or systemic vasculitides disorders.

Genetics has a more definitive role in primary hypertension than in secondary hypertension. Of 192 children and adolescents with primary hypertension, 49 percent had parents with primary hypertension and 10 percent had parents with secondary hypertension; and 24 percent and 46 percent of 84 children and adolescents with secondary hypertension had parents with primary and secondary hypertension respectively. Genetic factors also have a role in the development of some causes of secondary hypertension.

A detailed discussion on pathophysiology and pathogenesis of both forms of hypertension, e.g. primary or essential and secondary, is beyond the scope of this article. Evolution of hypertension involves a complex interplay of genetic and environmental factors that trigger and modulate various neural (central, peripheral and autonomic), hormonal renin-angiotensin II–aldosterone system (RAAS) and vascular (endothelium, endothelin, nitric oxide and other vasoactive substances) mechanisms and feedback loops. The interested readers may read the article written by Mukesh Singh et al on pathogenesis and clinical physiology of hypertension in *Cardiology Clinics* 2010 issue.

Low Birth Weight IUGR Babies and Association with Hypertension¹⁷⁻¹⁹

In a study of 95 children with new onset hypertension, Feig et al observed essential hypertension in low birth weight children than controls. On follow-up of 144 children with IUGR and 372 normal birth weight children at 6 years of age, Shankaran et al recorded hypertension in 24 percent of IUGR children and 16 percent of non – IUGR children. Franco et al on recording BP in 118 children between 8 and 13 years of age, observed hypertension in 38.1 percent of children born with low birth weight and in only 2.8 percent of children with normal birth weight. 9.5 percent of children born with low birth weight had prehypertension.

Obstructive Sleep Apnea and Hypertension in Children^{21,22}

Studies in children with obstructive sleep apnea (OSA) have documented intermittent increase in systemic and pulmonary vascular resistance and subsequent elevation of systemic and pulmonary pressures with remodeling and abnormal ventricular geometry and hypertrophy of the left and right ventricles (LV, RV).

Obesity and Hypertension in Children²³

Obesity in children and adolescents is associated with cardiovascular disease including hypertension, dyslipidemia, insulin resistance, glucose intolerance, type 2 diabetes mellitus and left ventricular hypertrophy. Reduction in

weight has been shown to result in lowering of both systolic and diastolic BPs.

Evaluation of BP in Children^{1-7,32-37}

The earliest recommended age for recording BP in children is 3 years. Before 3 years of age, BP recording on routine examination has technical difficulties. Application of cuff is difficult and measurements often are inaccurate. The cost of an accurate instrument to be used in this age group is another reason. BP measurement is essential below 3 years of age, if the child has a history of prematurity, IUGR, or any cardiac or renal problems. BP must be recorded twice in children over 3 years during every medical consultation.

The recommended instrument is conventional sphygmomanometer and the recommended method is the conventional auscultatory method over the brachials. The onset of the tapping Korotkoff (K1) sounds on auscultation indicates systolic BP and the disappearance of these sounds (K5) is now recognized as indicative of diastolic BP. In infants and young children less than 3 years, automated oscillometric BP instruments or the Doppler devices are often employed. Both systolic and diastolic BP must be recorded.

Techniques of BP Measurement

The ideal site for noninvasive external measurement of BP is brachial artery. Measurement devices applied over wrist and fingers are available, but the problem is the fact that systolic pressure increases and the diastolic pressure decreases in the distal arteries.

There are four measurement techniques:

1. The auscultatory method
2. The oscillometric method
3. The ultrasound technique and
4. The finger cuff method of Penaz.

The auscultatory method of listening to Korotkoff sounds using mercury sphygmomanometer is still considered the gold standard for BP measurement in office settings. As there is an official ban in the use of mercury in many developed nations, the mercury device used in auscultatory method is getting phased out in these nations. The available aneroid manometers are less accurate and they need frequent calibrations. New devices combining the features of both electronic and auscultatory devices known as “hybrid” sphygmomanometers have been developed where the mercury column is replaced by an electronic pressure gauge similar to oscillometric devices but the readings are obtained using a stethoscope and listening for the Korotkoff sounds.

First demonstrated by Marey in 1876, the oscillometric technique records the oscillations of pressure in a sphygmomanometer cuff during gradual deflation, where the point of maximal oscillation corresponds to the mean

intra-arterial pressure. It must be remembered that the oscillations begin at approximately systolic pressure and continue below diastolic and both these pressures are derived using an empirical algorithm, which is different for different commercial brands. However, there has been good agreement in the estimated BP levels when compared with intra-arterial evaluation and auscultatory Korotkoff sound methods. This method is better suited for ambulatory monitoring and home monitoring devices as there is no placement of a transducer over brachial artery, but its main drawback is its total unreliability during physical activities.

With ultrasound devices, when sphygmomanometer cuff with an ultrasound transmitter and receiver kept inside is deflated after placement over the brachial artery, systolic pressure gets recorded when there is a Doppler phase shift arising due to the movement of the arterial wall and the diastolic pressure at the point of diminution of arterial motion. This method with minor modification is helpful in recording systolic pressure in infants and young children.

In the Photo-Plethysmograph Finger Cuff Method of Penaz, arterial pulsation in a finger is recognized by the plethysmograph under a pressure cuff. The oscillations of pressure in the cuff are measured and they resemble the intra-arterial pressure wave. Finometer and portapres recorders are commercially available and their systolic and diastolic estimates have been validated against intra-arterial pressures in many reports.

Blood Pressure Measurement

Though there is no consensus regarding the position in which BP is to be taken, most of the guidelines on BP measurement recommend evaluation of BP in the sitting position. In adults, there are a few studies that indicate a higher diastolic pressure of 10 mm Hg in the sitting position in younger subjects. This difference between sitting and supine readings is only 2 mm Hg in older individuals around 70 years of age.

The position of the arm in which the cuff is applied is also important. BP reading is higher by 5 mm Hg when the arm is kept vertically down than when it is kept in the horizontal position. The subject must be sitting with a support behind as in an individual sitting bolt upright without a back support the diastolic reading is noted to be higher by 6.5 mm Hg.

Choice of BP Cuff (Table 1)

Choosing the appropriate sized cuff is vital to record accurate BP in children. Inappropriately small sized cuff gives abnormal elevated readings whereas bigger sized cuffs give low inaccurate readings. The inflatable bladder inside the cuff should have an ideal width of at least 40 percent

Table 1: Recommended dimensions for blood pressure cuff bladder sizes

Age range	Bladder width (cm)	Bladder length (cm)	Max. arm circumference (cm)*
Newborn	3–4	6–8	<6–10
Infant	5–6	12–15	15
Child	8–9	18–21	16–22
Smalladult	10	24	22–26
Adult	13	30	27–34
Largeadult	16	38	35–44
Thigh	20	42	45–52

* Calculated so that the largest arm would still allow bladder to encircle arm by at least 80 percent

of the midarm circumference and a cuff length that is 80 percent to 100 percent of the arm circumference.

The American Heart Association, National High Blood Pressure Education Program (NHBPEP) and fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents recommend cuffs of different sizes standardized to the arm circumference (Table 1).

Specific Recommendations for Office BP Measurement in Children and Adolescents

- The recommended method is auscultatory
- Use K1 for systolic BP and K5 for diastolic BP
- If the oscillometric method is used, the monitor needs to be validated
- If hypertension is detected by the oscillometric method, it needs to be confirmed using the auscultatory method
- Use the appropriate cuff size according to arm width (40% of the arm circumference) and length (4–8 cm, 6–12 cm, 9–18 cm, 10–24 cm, to cover 80–100 percent of the individual's arm circumference).
- Children above 3 years of age who are seen in a medical setting should have their BP measured. In younger children, BP should be measured under special circumstances that increase the risk for hypertension: under neonatal conditions requiring intensive care, congenital heart disease, renal disease, treatment with drugs known to raise BP and evidence of elevated intracranial pressure.

Classification of Blood Pressure (Table 2)

As body size is one of the known essential determinants of blood pressure in children, besides age and sex of the child, the height percentile chart is to be referred to determine if BP is normal. Classification of blood pressure was constructed from large epidemiologic studies that considered age, gender, height, and body weight.

Table 2: Classification of elevated blood pressure in children and adolescents ≤ 17 years of age

Classification	<i>Blood pressure value as percentile for age, sex and height taken at different visits</i>
Normal	<90th percentile
Prehypertensive	≥ 90 th and <95th percentiles (consistently recorded on three visits)
Hypertensive	≥ 95 th percentile
Stage 1 hypertension	95th to 99th percentile +5 mm Hg
Stage 2 hypertension	≥ 99 th percentile +5 mm Hg

Table 3: Age related causes of hypertension in children and adolescents

Age group	Common causes of hypertension
Neonate	Renal artery thrombosis or stenosis, renal malformations, coarctation of the aorta, bronchopulmonary dysplasia
Infants to 6 years	Renal parenchymal diseases, coarctation of the aorta, renal artery stenosis
6–10 years	Renal parenchymal diseases, renal artery stenosis, essential hypertension
Adolescence	Essential hypertension, obesity, renal parenchymal diseases, renal artery stenosis

Table 4: Causes of acute and chronic sustained systemic arterial hypertension*Causes of pediatric hypertension*

<i>Acute</i>	<i>Chronic sustained</i>
<i>Renal</i>	
Acute poststreptococcal glomerulonephritis	Chronic nephritis/renal parenchymatous disease (many causes)
Hemolytic uremic syndrome	Obstructive uropathy
Acute nephritis (many causes)	Chronic pyelonephritis
Interstitial nephritis	Reflux nephropathy
Acute pyelonephritis	Polycystic kidney disease
Acute kidney injury	Multicystic dysplastic, hypoplastic kidneys
Urinary tract obstruction	
<i>Vascular</i>	
Renal artery thrombosis	Renal artery stenosis–fibromuscular, atheromatous
Renal vein thrombosis	Extrinsic compression of renal vessels
Patent ductus arteriosus	Aortic coarctation
Vasculitis syndromes	Vasculitis syndromes
<i>Endocrine</i>	
Cushing syndrome	Congenital adrenal hyperplasia: 11 β - or 17 α -hydroxylase deficiency
	Cushing's syndrome -
	Hyper-/hypothyroidism
	Mineralocorticoid excess
	Glucocorticoid remediable aldosteronism
	Liddle's syndrome
<i>Tumors</i>	
	Pheochromocytoma, Neuroblastoma (catecholamine –secreting tumors)
	Juxtaglomerular cell tumors
	Mesoblastic nephroma
	Adrenal tumors- aldosterone-producing adenomas, adrenal carcinoma
<i>Genetic syndromes or inherited disorders</i>	
Williams syndrome	Williams syndrome
<i>Acute neurological conditions</i>	Tuberous sclerosis
Encephalitis	Neurofibromatosis
Meningitis	
Raised intracranial pressure	
Guillain-Barre syndrome	
Familial dysautonomia	
Postseizure	
Severe emotional stress	
After intracranial surgery	
Intracranial trauma	
Poliomyelitis

Metabolic

Hypercalcemia
Hypernatremia
Acute intermittent porphyria

Drugs/Ingestions/Toxic

Ingestions
Prescription medications
Sympathomimetic amine containing drugs:
Decongestants, eye drops
Eating foods with a high tyramine content (aged cheese, pickled herring, beer, red wine) while taking monamine oxidase inhibitors
Over-the-counter medications
Steroids - contraceptive pills with estrogen, anabolic steroids, therapeutic
Illicit drugs: Cocaine,
Amphetamines, phencyclidine
Heavy metals: Mercury, lead
Licorice
Hypervitaminosis A or D

Prescription medications –steroids, contraceptives
Over-the-counter medications
Sex hormones testosterone, anabolic steroids
Excess licorice ingestion,
Ketoconazole administration
Herbal therapies
Dietary supplements
Illicit drugs

Miscellaneous

Bronchopulmonary dysplasia
Pre-eclampsia
Stevens-Johnson syndrome
Leukemia
Burns
Prolonged bedrest and traction
Pseudoxanthoma elasticum
Genitourinary tract surgery
Closure of abdominal wall defects
Orthopedic limb lengthening
Familial chloride-losing enteropathy
Cyclic vomiting
Extracorporeal membrane oxygenation
Surgical/trauma/injury
Intravascular volume overload

The diagnosis of hypertension is made only after recording of two further high readings above the 95th percentile at different visits after the initial abnormal reading. The causes of hypertension in children are given in Tables 3 and 4.

Ambulatory Blood Pressure Monitoring in Children and Adolescents²³⁻²⁵

Another recent advance in the field of pediatric hypertension is the increasing use of ambulatory blood pressure monitoring (ABPM) in children and adolescents to identify those hypertensive children who otherwise escape being recognized as hypertensives because of repeatedly and randomly recorded apparently normal BP readings using conventional devices and techniques at office or home. As BP gets affected in children over 24 hours by factors like physical activity, emotional changes, posture,

time of day, level of wakefulness and others, in recent years considerable interest and efforts have been put into record BP continuously round the clock by developing newer measurement devices that can record the ambulatory BP. ABPM data published in recent years have identified children with elevated blood pressures who would have otherwise been passed off as normotensive children. The masked hypertension is a condition in which subjects classified as normotensive by conventional office or clinic measurement are hypertensive with ambulatory BP monitoring or self-measurement. This entity of masked hypertension is a new subentity which is different from white coat hypertension and can be identified only with 24-hour BP record patterns. Ongoing researches in “unmasking” the hidden or occult hypertension in children by ABPM will help to formulate normative data and percentile charts and to establish investigative and therapeutic guidelines

to abolish or minimize the risk of target organ damage. It is hoped that ABPM when indicated will help in fine tuning and establishing a correct therapeutic approach in further reducing the risk of target organ damage. Definite indications for ABPM are being developed.

Clinical Evaluation of Children with Systemic Arterial Hypertension^{1-7,32,37} (Tables 5 to 8)

Evaluation of children and adolescents identified as having hypertension always starts with history and physical examination. History sheet must record all the following details. History and physical examination must try to find an identifiable cause, target organ involvement. The following recommendations are made by the European Society of Hypertension in 2009.

Assessment of Hypertensive children for Comorbidities (Table 9)

In all hypertensive children and more so in those with obesity, family history of hypercholesterolemia or hypertriglyceridemias, fasting blood lipid panel and sugar, glucose tolerance test or glycosylated hemoglobin (HgbA1C) must be estimated.

*Uric Acid—Role in New Onset Pediatric Essential Hypertension^{17,20}

There are scientific evidences to correlate elevated uric acid levels in serum with new onset primary essential hypertension in children and adolescents. Uric acid is postulated to cause hypertension in two phases—firstly it predominantly causes peripheral vasoconstriction. In the

Table 5: Clinical history sheet-data to be recorded in pediatric hypertension
(European Society of Hypertension Recommendations – J Hypertension 2009;27:1719-42)

Symptoms suggestive of target organ damage	Headache, epistaxis, vertigo, visual impairment Facial palsy, fits, strokes Dyspnea
Symptoms suggestive of secondary hypertension	Dysuria, thirst/polyuria, nocturia, hematuria Edema, weight loss, failure to thrive Palpitations, sweating, fever, pallor, flushing Cold extremities, intermittent claudication Virilization, male pseudohermaphroditism and primary amenorrhea Sleep history Snoring, apnea, daytime somnolence
Risk factors to be identified	Physical exercise Dietary habits Smoking, alcohol Drug intake: Anti-hypertensives, steroids, cyclosporine, tacrolimus or other tricyclic antidepressants, atypical antipsychotics, decongestants Oral contraceptives, illegal drugs Pregnancy
Perinatal history	Birth weight, gestational age, oligohydramnios, anoxia, umbilical artery catheterization
Previous history	Hypertension Urinary tract infection, renal or urological disease Cardiac, endocrine (including diabetes) or neurological disease Growth retardation
Family history	Hypertension Cardiovascular and cerebrovascular disease Diabetes mellitus Dyslipidemia Obesity Hereditary renal disease (Polycystic kidney disease) Hereditary endocrine disease (pheochromocytoma, glucocorticoid-remediable aldosteronism, multiple endocrine neoplasia type 2, von Hippel-Lindau) Syndromes associated with hypertension (neurofibromatosis)

Table 6: History suggestive of a secondary cause of childhood hypertension

<i>Positive history</i>	<i>Possible cause/s</i>
Past history of UTI, symptoms of recent/current UTI	Reflux nephropathy, chronic and acute pyelonephritis
Acute onset of hematuria	Glomerulonephritis, renal vein thrombosis
Pyoderma, sore throat preceding onset of oliguria, hematuria, pedal edema, puffiness of eyelids	Poststreptococcal glomerulonephritis
Fever –recurrent, arthralgias/arthritis, rash	Vasculitis, SLE
Abdominal or Renal trauma	Renal artery stenosis, renal infarction
Mouth breathing, excessive snoring	Obstructive sleep apnea disorder associated hypertension
Recurrent and frequent spells of facial flushings, pallor, sweating, palpitations	Pheochromocytoma
Sweating, heat intolerance, tremors, weight loss	Hyperthyroidism
Precocious puberty	Adrenal disorder
Renal transplant	Transplant renal artery stenosis
Muscle cramping, constipation	Hyperaldosteronism
Abdominal radiation	Radiation nephritis, Renal Artery Stenosis
Abdominal mass or distension	Polycystic kidneys, hydronephrosis, renal and urinary tract obstructive disorders, Wilms' tumor, neuroblastoma, pheochromocytoma (rare)
Drugs: Medications - steroids, sympathomimetics, contraceptive pills	Drug induced hypertension
Substance abuse	Anabolic steroids, cocaine, amphetamines, phencyclidine
Toxins: Lead exposure	Lead induced hypertension
Positive family history	
Hypertension	Essential hypertension
Renal disease	Many congenital renal disorders

Table 7: Physical examination—Data to be recorded
(European Society of Hypertension Recommendations) – J Hypertension 2009;27:1719-42)

<i>General</i>	<i>Age, Sex, height, weight, body mass index</i>
External features of syndromes/conditions associated with hypertension	Neurofibromatosis, Klippel-Trenaunay-Weber, Feuerstein-Mims, von Hippel-Lindau, multiple endocrine neoplasia, pseudoxanthoma elasticum, Turner, William, Marfan, Cushing, hyperthyroidism, lupus, vasculitis, congenital adrenal hyperplasia
Cardiovascular examination	Pulse and BP measurement in both arms and legs Bruits/murmurs– heart, abdomen, flanks, back, neck, head Signs of left ventricular hypertrophy or cardiac failure
Abdomen	Masses – Wilms, neuroblastoma, pheochromocytoma, autosomal dominant and recessive polycystic kidney disease, multicystic kidney dysplasia, obstructive uropathy Hepatosplenomegaly – autosomal recessive polycystic kidney disease
Neurological examination	Fundoscopy for hypertensive changes and retinal hamartoma (von Hippel-Lindau) Evidence of VIII nerve palsy Other neurological defects including stroke

Table 8: Physical findings as indicators of the possibility of presence of a secondary cause of childhood hypertension

<i>Region</i>	<i>Physical findings on clinical examination</i>	<i>Possible cause/s</i>
Height/weight	Growth retardation	Chronic renal failure
	Obesity (high BMI)	Primary hypertension
	Truncal obesity	Cushing syndrome, insulin resistance syndrome
Vital signs	Tachycardia	Hyperthyroidism, pheochromocytoma neuroblastoma, primary hypertension
	Decreased lower extremity pulses; Drop in BP from upper to lower extremities	Coarctation of the aorta
Eyes	Retinal changes	Severe hypertension, more likely to be associated with secondary hypertension
Ear, nose and throat (ENT)	Adenotonsillar hypertrophy	Possible association with sleep-disordered breathing (sleep apnea), snoring
Head and neck	Moon facies	Cushing's syndrome
	Elfin facies	Williams syndrome
	Webbed neck	Turner syndrome
	Thyromegaly	Hyperthyroidism
Skin	Pallor, flushing, diaphoresis	Pheochromocytoma
	Acne, hirsutism, striae	Cushing syndrome, anabolic steroid abuse
	Café-au-lait spots	Neurofibromatosis
	Adenoma sebaceum	Tuberous sclerosis
	Malar rash	Systemic lupus erythematosus
	Acanthosis nigricans	Type 2 diabetes
	Widely spaced nipples	Turner syndrome
Chest	Heart murmur	Coarctation of aorta
	Friction rub	SLE and collagen vascular diseases (pericarditis), end stage renal disease
	Apical heave	Left ventricular hypertrophy, chronic hypertension
Abdomen	Truncal obesity, Striae	Cushings, exogenous steroids
	Mass	Wilms tumor, neuroblastoma, pheochromocytoma
	Palpable kidneys	Polycystic kidney disease, hydronephrosis, multicystic- dysplastic kidney, mass
	Epigastric/flank bruit	Renal artery stenosis
Genitalia	Ambiguous/virilization/hypogonadism	Congenital adrenal hyperplasia
Extremities	Joint swelling	SLE and collagen vascular diseases
	Muscle weakness	Hyperaldosteronism, Liddle syndrome

second phase, it induces renal afferent arteriosclerosis and subsequent altered pressure natriuresis leading to sodium dependent hypertension. Studies with allopurinol treatment are under way to find out the BP response to lowering of uric acid levels as preliminary data have suggested such a positive response.

Birth weight was noticed by Feig et al to have an inverse relationship with uric acid levels. Hence, there is considerable speculation that raised uric acid levels may signal early onset of hypertension in those who were born underweight.

Target Organ Damage²⁶⁻³¹

Pediatricians have always been aware of the target organ complications like acute encephalopathy, left ventricular failure with pulmonary edema and acute renal failure arising as a result of abrupt and acute elevations of blood pressure of brief durations in children. In developing countries, many children below 8 years of age present with seizures, altered sensorium, acute pulmonary edema secondary to hypertension of poststreptococcal glomerulonephritis.

Table 9: Investigative work up (Recommended by guidelines)^{1-7,32-37}*Routine tests in all hypertensive children*

- Full blood count
- Urinalysis
- Plasma sodium, potassium and calcium, urea, creatinine
- Serum uric acid – primary essential hypertension*
- Fasting plasma glucose
- Serum lipids (cholesterol, LDL cholesterol, HDL cholesterol)
- Fasting serum triglycerides
- Chest X-ray, ECG and 2-D echocardiography
- Renal ultrasound for renal parenchymatous diseases, anomalies, hydronephrosis, Wilms tumor, neuroblastoma

Next line of Investigations

Dimercaptosuccinic acid (DMSA) scan	Chronic pyelonephritis
Renal Doppler ultrasound, MRI	Renal artery stenosis
Digital subtraction angiography	
Markers for target organ damage	Left ventricular hypertrophy- LV mass
Plasma renin concentration	Increased in renal artery stenosis; decreased in primary hyperaldosteronism, dexamethasone-suppressible hypertension
Plasma aldosterone concentration	Increased in renal artery stenosis, primary hyperaldosteronism, dexamethasone-suppressible hypertension
Plasma deoxycorticosterone	Increased in congenital adrenal hyperplasia
Urinary steroids	Mineralocorticoid excess, congenital adrenal hyperplasia

Sophisticated investigations following the initial work up

Color Doppler ultrasonography	Estimation of carotid wall intima-media thickness
Urinary catecholamines, metanephrines, VMA	Pheochromocytoma, neuroblastoma
Pheochromocytoma	
Urinary normetanephrine with a reported sensitivity of 96.9%, platelet norepinephrine –Sn. of 93.8%, urinary norepinephrine –Sn. of 77.7%	
Renal arteriogram	Renal artery stenosis
Captopril primed MAG3 labeled isotope renal scan	Renal artery stenosis
Renal vein renin estimation	
CT scan, MRI	Tumors
Radioisotopic ¹³¹ I-metaiodobenzyl guanidine scanning	Pheochromocytoma Sn – 83.7% (False positives in neuroblastoma and carcinoids)
Molecular genetic studies	Apparent mineralocorticoid excess, Liddle's syndrome, etc.

The effects of long and sustained hypertension on arterial vessels, heart, kidneys, brain and retina causing significant morbidity and mortality in adults are well studied and documented. The risks for target organ damage have been worked out by elegant and robust studies in adult hypertension. Besides hemodynamic alterations, varied factors like duration and severity of hypertension, family and hereditary predisposition, ethnicity play significant role in determining the degree of target organ damage. The importance of prevention and early treatment of hypertension in preventing or reversing these target organ damages by appropriate measures has been adequately proved.

In children and adolescents with hypertension, these questions are yet to be answered. The need for very early identification of target organ damage in hypertensive children and adolescents has become a recent priority in advanced countries. Recently published studies in children with hypertension have focused their attention in this direction. A definitive and conclusive evidence of onset of target organ damage in early childhood hypertension will help the pediatric community and specialists to take a rational decision regarding initiation of antihypertensive drug treatment without delay with the sole objective of reducing the risk of target organ damage and improving their quality of life in future. Moreover, monitoring

of the trends of these recognized markers of organ damage during drug therapy will also indicate the therapeutic response and the need for change or addition of drugs.

In adults, the two markers of cardiac damage secondary to hypertension are left ventricular mass (LVM) and carotid wall intima-media thickness. Studies now are in progress to determine the left ventricular mass in various age groups in children and adolescents and to correlate the same with weight, lean body mass, and other growth and maturation parameters of these children and in hypertensive children. Adiposity has correlation with increased left ventricular mass. Sustained ambulatory BP elevations in adolescents are reported to have increased LVM when compared to normotensive adolescents. Concentric left ventricular hypertrophy (LVH) is considered indicative of end organ damage in childhood hypertension. Echocardiatic measurement of LVM and its (LVMI) correlated to height of the child have shown increased values in 41.1 percent and 15.5 percent of hypertensive children.

Carotid wall and femoral intima-media thickness (c-IMT and f-IMT) are being assessed in children in all stages of hypertension as markers of cardiac endovascular and organ damage. Studies by Litwin et al have shown increased c-IMT (more than 2 S.D) in 38.8 percent and f-IMT (more than 2 S.D) in 17.5 percent of hypertensive children and also their good correlation with 24 hours SBP and pulse pressure. They also demonstrated functional carotid vascular changes like arterial distensibility, elasticity and compliance in hypertensive children. Meyer et al made two observations: (1) Increased c-IMT had association with increased BP in children and (2) a significant increase in c-IMT in obese children as compared to controls. However, c-IMT is not currently recommended in the fourth report of National High Blood Pressure Education Program (NHBPEP) working group as a screening procedure in childhood hypertension.

In adults with hypertension and diabetes, microalbuminuria and urinary albumin excretion (UAE) are routinely evaluated as they correlate well with renal and cardiovascular morbidity. Current and future studies in pediatric age group will be able to define the importance of these markers in predicting target organ damage.

TREATMENT OF HYPERTENSION³²⁻³⁷

Principles of Treatment of Hypertension in Children

1. Treatment of the primary cause of secondary hypertension.
2. Non-pharmacological measures (lifestyle modifications).
3. Pharmacological or drug treatment.
4. Treatment of hypertensive urgencies and emergencies.

Non-Pharmacological Measures (Lifestyle Modifications) (Table 10)

In all children with primary or essential hypertension, a trial of non-pharmacological measures is warranted to bring down BP. When the repeatedly recorded BP levels in a child fall between 90th and 95th percentile for that age (prehypertension), lifestyle changes are recommended and the compliance ensured. These activities are also applicable to children who have established hypertension with BP recordings more than 95th percentile.

Table 10: Dietary and certain life style modifications in lowering BP – Currently available evidence from literature

Persuasive evidence

- Dietary sodium intake 2.3 g (<100 mmol) per day*
- Dietary potassium intake 4.7 g (>120 mmol) per day
- Increased Omega-3 polyunsaturated fat from natural sources
- Indian vegetarian diet, DASH diet (USA), Mediterranean diet (Europe), Ornish diet (USA)
- Moderation of alcohol intake in those who take alcohol to <2 drinks/day in adolescent boys and young men and <1 drink/day in women
- Stress management

Suggestive evidence

- High fiber diet
- Carbohydrate
- Exercise at least 30 minutes of moderate activity most days of the week

Limited or equivocal evidence

- Increased dietary calcium and magnesium intake through natural sources
- Low saturated fat diet
- Omega-6 unsaturated fat, Monounsaturated fat
- Low cholesterol diet
- Increased vegetable protein instead of carbohydrates
- Yoga, meditation and other relaxation techniques

* Children and adolescents are reported to be less responsive than adults to salt restriction.

Weight reduction: Demonstrable fall in BP has been documented in those overweight children who shed more than 4 to 7 kg of their original weight and maintained the weight loss in a determined manner. Altered sympathetic tone, reversal of endothelial dysfunction and improved metabolic responsiveness to insulin have been incriminated in bringing about this BP lowering effect.

Exercise: Four times a week regular exercise and physical activities for a duration of 30 to 40 minutes have shown perceptible improvement in BP. Yoga and biofeedback as

Table 11: Indications for drug therapy in pediatric and adolescent hypertension

- Stage 2 hypertension
- Symptomatic hypertension
- Secondary hypertension
- Hypertensive target-organ damage
- Diabetes (types 1 and 2)
- Persistent hypertension despite nonpharmacologic measure

stress reduction techniques have effect in lowering BP in highly motivated, compliant children and adolescents.

Pharmacological or Drug Treatment (Table 11)

Before the initiation of drug treatment of hypertension in children without a remediable cause, 2-weekly BP response to a trial of closely supervised nonpharmacological measures for a period of 3 to 6 months must be evaluated. When the predetermined BP goals are not achieved, the drug treatment is initiated with a single drug at its recommended lowest therapeutic dosage. Its effect on lowering of BP is monitored on alternate days in the first 2 weeks and then every 2 weeks. The dosage of medications is stepped up to the maximum recommended dosage once in 2 weeks and occurrence of any adverse effects is noted and taken into account.

As there are no evidence based data on the long term benefits of pharmacologic therapy of childhood hypertension in preventing the development or occurrence of strokes, cardiovascular diseases and progressive renal damage, pediatricians must weigh the benefits of treatment against the adverse effects of long term use of antihypertensive drugs on growth and development of children and adolescents.

Antihypertensive therapy with a single drug or more than one is recommended in children and adolescents with:

1. Symptomatic hypertension when symptoms such as headaches or seizures are related to elevated blood pressure.
2. Secondary hypertension.
3. Stage 2 hypertension, defined as blood pressure levels that are 5 mm Hg greater than the 99th percentile.
4. Stage 1 hypertension persisting after four to six months of nonpharmacologic therapy.
5. Stage 1 hypertension in patients with diabetes mellitus or other conditions that increase the risk of heart disease or stroke, such as high cholesterol or lipids.
6. Prehypertension with more than one additional risk factor for heart disease or stroke.
7. Physical signs of hypertension, such as a thickened wall of the left ventricular chamber of the heart.

From the various classes of available antihypertensive drugs, the most appropriate drug in terms of therapeutic efficacy, safety, cost and above all the acceptance and tolerance of the child is chosen. The drug that is so individualized is started with the initial recommended dose with monitoring of the BP response to this drug. If there are no adverse effects to this drug and if BP is not adequately brought down to normal levels, the dose is stepped up every third or fourth day till optimum BP control is achieved or till the maximum recommended dose for that drug is reached. If no desired effect is seen, another drug with complementary action is added and the above process is repeated. The subsequent steps are given in the table. This stepped care approach recommended by NHBPEP is still followed. Before increasing the dose or adding another drug, enough attention must be given to the drug compliance and adherence to the management protocol.

Angiotensin-Converting Enzyme Inhibitors (ACEIs) (Table 12)

Among the available ACEIs, Captopril was the first orally available drug to be used since in early 1980S to treat

Table 12: Pharmacological choices for treatment of hypertension in children and adolescents

Class of drugs: Angiotensin converting enzyme inhibitors (ACEIs)

Drugs	Initial dose	Maximum dose	Interval	Side effects and remarks
Captopril	0.3-0.5 mg/kg/day	6.0 mg/kg/day	bid-tid	CI: children with bilateral RAS
Enalapril	0.04 mg/kg/day-up to 5 mg/day	0.6 mg/kg/day up to 40 mg/day	qd	Hyperkalemia, cough, angioedema, decrease in GFR, loss of taste, thrombocytopenia
Lisinopril	0.07 mg/kg/day-up to 5 mg/day	0.6 mg/kg/day up to 40 mg/day	qd	
Benazepril	0.2 mg/kg/day-up to 10 mg/day	0.6 mg/kg/day up to 40 mg /day	qd	
Fosinopril		0.6 mg/kg/day up to 40 mg/day	qd	Periodic monitoring of serum chemistries
Quinapril	5-10 mg/day	up to 80 mg/day	qd	
Ramipril	2.5 mg/day	20 mg/day	qd	

children including neonates with hypertension. Captopril has been employed successfully for a number of years in the proper control of both neonatal and childhood hypertension. Though found to be safe and effective, it has to be administered three times a day because of its shorter duration of action. Cough is an often reported side effect. It should not be used, if there is any suspicion of presence of bilateral renal artery stenosis.

Longer acting ACEIs - enalapril and lisinopril, being nonsulphydryl containing ACEIs, cause lesser incidence of side effects than captopril. While enalapril gets activated to enalaprilat by hydrolysis after gastrointestinal absorption, lisinopril needs no bioactivation. Its absorption is slower than enalapril. Enalapril and lisinopril are safe and effective in lowering BP in controlled trials. Enalapril has been effectively employed in hypertensive treatment of neonates and children. Ramipril has proved its safety and efficacy in lowering BP and reducing proteinuria in children with hypertensive chronic renal failure. Fosinopril and quinapril have been tried less often and used only in a few smaller trials.

Angiotensin II Receptor Blockers (ARBs) (Table 13)

Currently many trials are under way evaluating the usefulness of ARBs in childhood hypertension. A few studies with losartan, irbesartan, candesartan and valsartan have shown promise. With losartan treatment, significant

reductions in DBP were reported in children with estimated GFRs 30 ml/min per 1.73 m² or more. Smaller trials have reported the efficacy of other ARBs like irbesartan (75-150 mg/kg/day) and candesartan in childhood hypertension. Both of these agents reduced BP and proteinuria seen in some of the treated children. valsartan has been reported to effectively lower both SBP and DBP compared with placebo in 1 to 5 years old children. The drugs are currently very costly.

Calcium Channel Blockers (CCBs) (Table 14)

Calcium channel blockers (CCBs) by inhibiting calcium entry into the vascular smooth-muscle cell via a voltage-gated channel causes direct vasodilatation. They are widely used precisely because of their generally recognized safety profile. Among the available three categories of CCBs-dihydropyridines (e.g. nifedipine), phenylalkylamines (e.g. verapamil) and benzothiazepines (e.g. diltiazem), the most widely used drugs in this class are the dihydropyridines. Amlodipine, because of its enhanced binding to the calcium channel, has prolonged elimination half-life (30 hours) and extended duration of action. In a dose of 0.05 to 0.5 mg/kg per day, it is given in once daily dosage and hence considered by most pediatricians as an optimal CCB agent for use in children. As no liquid formulation is available for use, it is only prescribed for children who can swallow tablets. Flushing, headaches, migraines,

Table 13: Pharmacological choices for treatment of hypertension in children and adolescents

<i>Class of drugs: Angiotensin II receptor blockers (ARBs)</i>				
<i>Drugs</i>	<i>Initial dose</i>	<i>Maximum dose</i>	<i>Interval</i>	<i>Side effects and remarks</i>
Losartan	0.75 mg/kg/day up to 50 mg/day	1.4 mg/kg/day up to 100 mg/day	qd	CI: children with bilateral RAS, pregnancy
Irbesartan	6-12 yrs: 75 mg 6-12 yrs: 150 mg qd	>12 yrs: 150 mg >12 yrs: 300 mg		Dizziness, drowsiness, headache, nausea, dry mouth, abdominal pain loss of taste, hyperkalemia, thrombocytopenia
Valsartan	1.3 mg/kg/day up to 40 mg/day	2.7mg/kg/day up to 160 mg/day	qd	
Candesartan	4-8 mg/day	32 mg/day	qd	
Olmesartan	2.5 mg/day	40 mg/day	qd	

Table 14: Pharmacological choices for treatment of hypertension in children and adolescents

<i>Class of drugs : Calcium channel blockers (CCBs)</i>				
Amlodipine	0.05 mg/kg/day 6-7 yrs: 2.5 mg/day	0.5 mg/kg/day up to 10 mg/day	qd	Headache, dizziness, flushing, nausea, gingival hyperplasia, mild tachycardia, swelling of the lower legs or feet
Nicardipine				
Isradipine	0.05 - 0.15 mg/kg/day	0.8 mg/kg/day up to 20 mg/day	tid - qd	
Nifedipine –extended release	0.25 -0.5 mg/kg/day	3 mg/kg/day	bid - qd	
Felodipine	2.5 mg/day	10 mg/day	qd	

peripheral edema are common side effects than gingival hyperplasia, nausea and vomiting and chest pain.

Beta-Adrenergic Blockers (β -ABs) – Selective and Nonselective and α - and β - Adrenergic Blocking Agents (Table 15)

Beta adrenergic blockers (β -ABs) alter central and peripheral sympathetic activity, inhibit renin release, lower blood pressure via a number of mechanisms, reduce cardiac output, and potentiate the action of natriuretic peptides thereby lowering BP in hypertensive subjects. Earlier introduced β -ABs like propranolol have been in use for many years but its non-selectivity is associated with a potential risk of precipitating bronchospasm. Pediatric hypertension has been treated for many years with propranolol. It

is contraindicated in asthma and heart failure. Propranolol may cause hypoglycemia and night terrors. It impairs glucose tolerance and alters lipid profile adversely by lowering HDLP-cholesterol and raising plasma triglycerides. It reduces the ability to perform physical activity.

The reported adverse drug reactions of β -blockers are fatigue, depression, dizziness, and light headedness, bradycardia, postural hypotension, cold extremities and nausea. Nowadays, β -adrenergic blockers are not as widely advocated for treatment of pediatric hypertension as calcium channel blockers or ACE inhibitors. This may be due to questions regarding long-term effects of β -blockers on growth and lipid profiles, and their tendency to cause drowsiness. They are used only when CCBs and ACEIs prove ineffective.

Table 15: Pharmacological choices for treatment of hypertension in children and adolescents

Class of drugs: Beta-adrenergic blockers (BABs)				
Selective β -Blockers				Bradycardia, bronchospasm, congestive cardiac failure, hypoglycemia, hyperkalemia, nightmares, confusion
Metoprolol	1-2 mg/kg/day	6 mg/kg/day	bid	
Atenolol	0.5-1 mg/kg/day	2 mg/kg/day up to 100 mg/day	qd -bid	
Nonselective β -Blockers				Hyperkalemia, nightmares, confusion, depression, altered serum lipoprotein concentrations
Propranolol	1 mg/kg/day	16 mg/kg/day up to 640 mg/day	bid-tid	
Metoprolol	1 mg/kg/day	5 mg/kg/day		
Atenolol	1 mg/kg/day	8 mg/kg/day	qd -bid	
Nadolol	0.5 mg/kg/day	4 mg/kg/day		
Prazosin	Prazosin	Prazosin	Prazosin	Hypotension, tachycardia, fluid retention
Doxazosin	Doxazosin	Doxazosin	Doxazosin	
Terazosin	Terazosin	Terazosin	Terazosin	
Phentolamine	Phentolamine	Phentolamine	Phentolamine	
Phenoxybenzamine	Phenoxybenzamine	Phenoxybenzamine	Phenoxybenzamine	
Class of drugs: α - and β - adrenergic blocking agents				
Labetalol	2-3 mg/kg/day	10-12 mg/kg/day up to 1.2 g/day	bid	CI: Asthma, CHF and diabetes, carvedilol not CI in CHF
Carvedilol	0.1 mg/kg/dose up to 12.5 mg	0.5 mg/kg/dose up to 25 mg	bid	
Class of Drugs: Central α - adrenergic antagonists				
Clonidine	5-10 mcg/kg/day	25 mcg/kg/day	Bid tid	Rebound hypertension with sudden withdrawal of clonidine
Dry mouth, sedation				
α -Methyldopa	5-10 mg/kg/day	40 mg/kg/day	tid, bid	
Class of drugs: Peripheral α -adrenergic antagonists				
Prazosin	0.05 mg/kg/day	0.5 mg/kg/day	tid	All cause first dose hypotension
Doxazosin	1 mg/day	4 mg/day	qd	
Terazosin	1 mg/day	20 mg/day	qd	
Phentolamine	0.2 mg/kg/day	1.0 mg/kg/day		
Phenoxybenzamine	1 mg/kg/day	5 mg/kg/day		

In adult trials, β -ABs do not protect against heart attack more than other classes and are reported to be associated with a 14 percent increase in the risk of stroke. The use of cardioselective β -ABs such as atenolol and metoprolol do not cause this problem. They are effective as single agents or in combination with diuretic and/or ACEIs.

Labetalol and carvedilol with its additional peripheral α 1-adrenergic blocking action besides β -blocking action enhance blood pressure-lowering property. Labetalol is one of the most commonly prescribed agent for treating pediatric hypertensive emergencies.

Diuretics in Systemic Arterial Hypertension (Table 16)

Diuretics cause a decrease in systemic arterial pressure by reducing blood volume and decreasing peripheral vascular resistance in a sustained manner. They have been found to be most useful in hypertensive children with

renal diseases. The three commonly used diuretic groups of drugs are thiazides or thiazide like diuretics, loop diuretics and potassium sparing ones. Frusemide, commonly used loop diuretic, is employed in hypertensive children with less than 50 percent of residual renal function. Hypokalemia is its major disadvantage. Frusemide when given by rapid intravenous push may cause ototoxicity. In preterms, frusemide administration may be associated with nephrocalcinosis. Spironolactone being an aldosterone antagonist has its use in those children with secondary hyperaldosteronism.

All diuretics are employed as add on therapy with one of the above classes of primary antihypertensive agents.

The responsibilities of treating pediatricians do not end with appropriate selection and institution of drug therapy in hypertensive children (Table 17). They need to periodically monitor on a long-term basis these children

Table 16: Class of drugs: Diuretics in systemic arterial hypertension

Chlorothiazide	10 mg/kg/day	20 mg/kg/day	bid	Hyperuricemia, hypokalemia, decreased urinary calcium excretion, hypovolemia, hypokalemia
Hydro chlorothiazide	0.5-1 mg/kg/day	2 mg/kg/day	qd	
Chlorthalidone	0.3 mg/kg/day	2 mg/kg/day up to 50 mg/day	qd	
Bumetanide	0.02-0.3 mg/kg/day	0.3 mg/kg/day		
Amiloride	5-10 mg/day	20 mg/day	qd	
Loop diuretics				
Furosemide	0.05-1 mg/kg/day	6 mg/kg/day		
<i>Aldosterone antagonists</i>				
Spironolactone	1-2 mg/kg/day	3.5 mg/kg/day up to 100 mg/day	qd/bid	Hyperkalemia
Eplerenone	25-50 mg per day	100 mg/day	qd/bid	
Triamterene	1-2 mg/kg/day	3-4 mg/kg/day up to 300 mg/day	bid	

Table 17: Drug options for initial therapy for hypertension in children

<i>Class of drugs</i>	<i>Patients' characteristics</i>	
ACE-Is/ARBs	First-line therapy	High plasma renin activity, unilateral renovascular hypertension, renal parenchymal disease, renal proteinuria, congestive heart failure, diabetes mellitus, gout, hyperlipidemia, reactive airway disease
	Avoid in	Pregnancy, bilateral RAS
CCBs	First-line therapy	Emergency hypertension (nifedipine), black race, diabetes mellitus, chronic obstructive lung disease, bronchopulmonary dysplasia, gout, hyperlipidemia, peripheral vascular disease. Renal transplant, therapy with anticalcinurin
	Avoid in	Contracted intravascular volume, high plasma renin activity, hyperdynamic circulation, anxiety, migraine (propranolol, nadolol), hyperthyroidism, neuroadrenergic tumors
β -blockers	Avoid in	Avoid in athletes and people with diabetes
	Adjunct second-line drug	Volume-dependent, low plasma renin activity, black race, oral contraceptive therapy, congestive heart failure
Diuretics	Avoid in	Avoid in athletes

ACE-I—angiotensin converting enzyme inhibitor; ARB—angiotensin receptor blocker; CCB—calcium channel blocker

Table 18: Individualized stepped care approach recommended for medical drug therapy for control of hypertension in children and adolescents

<i>Step 1:</i>	Start with the recommended initial therapeutic dose of the first selected drug If desired BP control is not achieved
<i>Step 2:</i>	Increase the dose of the first selected drug until the target BP is attained or maximum therapeutic dose is reached If desired BP control is not achieved
<i>Step 3:</i>	Add a second medication with complementary mechanism of action Increase gradually to its highest recommended therapeutic dose if necessary If desired BP control is not achieved
<i>Step 4:</i>	Add a third antihypertensive drug of a different class or consult a pediatrician with expertise in treating childhood and adolescent hypertension

for the adequate control of BP, occurrence of any adverse drug effects, electrolyte and other metabolic disturbances, compliance of drug therapy and non pharmacological measures and for any evidence of onset of target organ damage. Besides these, the need for periodic counseling regarding risk factors needs adequate stress in the management plan (Table 18).

Some children and adolescents with a good BP control for years with drugs and life style modifications, especially those who were obese to start with, may be considered for “step down” therapy. The drug dosage is gradually reduced over a period of months and if BP continues to remain normal even after this reduced dosage, a final attempt is made to totally withdraw the drug treatment in children. Once the drugs are totally withdrawn, these children must be encouraged to comply with the non-pharmacological measures and their BP status needs to be periodically checked.

Surgical options are considered for those children with secondary hypertension like renovascular hypertension, coarctation of aorta, tumors and surgically treatable endocrinal causes. They are appropriately referred.

Acute Hypertensive Crisis in Children^{38,39}

Hypertensive crises in children are pediatric emergencies that carry significant mortality and morbidity if recognized and treated late. It refers to clinical states in children with suddenly elevated blood pressure usually exceeding stage II hypertension levels in severity and requiring prompt institution of safe and appropriate rapidly acting antihypertensive drugs to normalize blood pressure in a stepwise manner so as to prevent or to revert impending or already existing effects on end organs like brain, kidneys and heart.

Table 19: Features of severe hypertension

Blood pressure	Above the 99.9th percentile or increasing rapidly
Target organs	Clinical features
Neurologic	Focal or generalized seizures, localizing signs, isolated facial nerve palsy, headaches
Cardiac	Pulmonary edema, left ventricular hypertrophy
Renal	Severe back or abdominal pain, abdominal or renal masses or bruits, decreasing renal function
Visual	Blurred vision, papilledema, retinal hemorrhages and exudates, constriction of retinal arteries

Acute hypertensive crisis is further classified into hypertensive emergencies and hypertensive crisis.

Hypertensive urgency refers to rapid, sudden elevation of high blood pressure in children without signs and symptoms of end-organ dysfunction. Hypertensive emergencies are defined as states of markedly elevated blood pressure associated with any one of the symptoms and signs of end-organ dysfunction such as seizures, headache with vomiting, altered sensorium and irritability, encephalopathy, facial palsy, intracerebral hemorrhage, breathlessness and cough with evidence of left heart failure and acute renal dysfunction (Table 19).

As evidence based treatment guidelines for hypertensive crisis from randomized control trials are not available, the selection of safe and rapidly acting effective first and second line drugs are based on pediatric observational studies of small sample size and extrapolated data from adult studies. Because of this limitation, it is essential that pediatricians have adequate knowledge of the current recommendations of expert groups in the selection of the most relevant, safe, speedy drugs, its dosage, route and frequency of administration so as to safeguard the child from adverse effects of hypertension on the target organs as well as from the undesirable side effects of the chosen drugs.

Pediatric emergency guidelines and institutional protocols call for controlled and stepwise reduction of highly raised BP over 48 hours and recommend the use of safe, effective and rapidly acting therapeutic agents often given parenterally. A 20 to 25 percent reduction of BP in the first 8 hours is ideal to prevent permanent end organ damage. Subsequent reduction in BP is gradually and carefully done with constant or regular, periodic monitoring over the next 40 hours and the target BP is aimed to be below 95th percentile in children without end organ damage or co-existing morbidities like diabetes mellitus or chronic renal failure and to be below 90th percentile in those without these above mentioned conditions.

The clinical features of hypertensive emergency are symptoms pertaining to target organ dysfunction. Invariably the parents are unaware of the gravity of the initial

symptoms like headache, vomiting, visual disturbances, cough with shortness of breath. Younger children cannot express these. Only when the child develops sudden seizures, altered sensorium, marked breathlessness, the parents seek medical attention. The pediatrician must always record the BP with appropriate sized cuff and reliable instrument in any child presenting with any of the symptoms pertaining to the target organs – CNS, CVS, kidneys or eyes. One of the commonest causes of hypertensive encephalopathy in children of tropical and developing countries is poststreptococcal glomerulonephritis secondary to pyoderma or pharyngitis. They present with a few days of oliguria, puffiness of upper eyelids in the mornings, mild pitting edema of feet preceding the onset of seizures or shock due left ventricular failure or marked breathlessness due to pulmonary edema. Other well documented precipitating causes are hypertensive reflux nephropathy, coarctation of aorta, vasculitides, renovascular thromboembolic events, renal artery stenosis, acute renal tubular necrosis and hemolytic uremic syndrome. Other features that may be seen are intracerebral hemorrhage, facial palsy, retinopathy, acute renal failure, hematuria and arrhythmias.

The pathogenesis of hypertensive crisis involves interplay of several complex neurohormonal and haemodynamic pathways, e.g. activation of renin-angiotensin-aldosterone system (RAAS), oxidative and mechanical microvascular damage, endothelial dysfunction, sympathetic neuronal overactivity, fluid overload, etc.

SUMMARY

The prevalence of systemic arterial hypertension is steadily increasing in children and adolescents. The need for accurate, frequent and sometimes 24-hour ambulatory measurement of BP is stressed. Secondary hypertension, especially secondary to renal parenchymal and renovascular disorders, accounts for majority of hypertensive children and needs extensive work-up. The increased risks of essential hypertension developing in children with obesity, sleep obstructive disorders and low birth weight are getting more attention and understanding.

Currently accumulating epidemiological data on childhood and adolescent hypertension emphasizes the need to recognize its presence early and treat effectively with appropriately chosen drugs (Table 20) and non-pharmacological measures to prevent and minimize the target organ damage

Table 20: Drugs used in the treatment of hypertensive emergencies

<i>Drug</i>	<i>Class</i>	<i>Route</i>	<i>Dose</i>	<i>Onset of action</i>	<i>Comments</i>
Sodium nitroprusside	Direct vasodilator	IV infusion	0.5-8 mg/kg/min	Within 30 seconds	Thiocyanate toxicity; inactivated by light
Labetolol	A and BB	V infusion	0.25-3 mg/kg/hr	5-10 minutes	CI: Asthma, CHF; may cause bradycardia
Nicardipine	CCB	IV infusion	1-3 mg/kg/min	Within minutes	Reflex tachycardia
Clonidine	Central alpha agonist	IV bolus	2-6 mg/kg/min	10 minutes	Sedation, dry mouth; rebound hypertension
Esmolol	Selective B1B	IV infusion	100-500 mg/kg/min	Within seconds	CI: Asthma, CHF; May cause bradycardia
Enalaprilat	ACEI	IV bolus	0.05-0.1 mg/kg/dose	15 minutes	CI: suspected bilateral RAS
Captopril	ACEI	oral	0.1 -0.2 mg/kg/dose	10-20 minutes	
Nifedipine	CCB	oral	0.25 mg/kg/dose	20-30 minutes	Reflex tachycardia; may cause unpredictable hypotension
Furosemide	Loop diuretic	IV bolus	0.5-2 mg/kg/dose	Within minutes	Hypokalemia
Minoxidil	Direct arteriolar vasodilator	oral	0.1-0.2 mg/kg/dose	5-10 minutes	Hypotension, fluid retention,
Hydralazine		IV	0.1-0.5 mg/kg	Within 30 minutes	
Diazoxide		IV	0.1-0.5 mg/kg	Within 30 minutes	Tachycardia, hypotension, flushing

A and BB—alpha and beta blocker; CCB—calcium channel blocker; BB—beta blocker; ACEI—angiotensin converting enzyme inhibitor; CI—contraindicated; RAS—renal artery stenosis

in heart, vessels and kidneys. There are emerging evidences to show childhood onset of end organ damage in hypertensive children such as left ventricular hypertrophy and arterial wall (intima-media) thickening in children with essential hypertension. Current research priorities are identification of biomarkers of target organ damage, genetic susceptibility and pharmacogenomics that determine therapy.

INTRODUCTION

Proteinuria is common in children and detection of abnormal amounts or types of protein in the urine is frequently the first sign of significant renal or systemic disease. Normally, a small amount of protein is present in the ultrafiltrate which is produced by the glomerulus and majority of it is absorbed by the tubules. At a normal GFR, approximately 1.4 kg of plasma proteins would be lost in the urine each day, if the kidneys were not capable of efficiently preventing the transglomerular trafficking of plasma proteins. The ability of the kidneys to retain proteins is essential for life. Normal urine contains not more than 150 mg of proteins per day.¹ Urinary protein excretion in excess of 100 mg/sq m/day or 4 mg/sq m/hr is considered abnormal in children. Approximately, 60 percent of urine proteins are derived from plasma whereas the remainder is produced by the kidney and the lower urinary tract. Physiological proteinuria means excretion of small amounts of protein in urine (less than 150 mg/day). Protein excretion is highest in infants, which decreases with age until late adolescence. This relatively high protein excretion observed in newborns represents tubular proteinuria, reflecting the immaturity of their renal function² (Table 1). Asymptomatic or isolated proteinuria is defined as proteinuria not associated with any signs or symptoms of renal disease.

MECHANISM OF PROTEINURIA

The glomerular capillary wall and the adjacent structures constitute the main barriers to the passage of macromolecules, including globulin and albumin. The barrier consists of the endothelial cells lining the capillary loops, the glomerular basement membrane and the visceral epithelial cells. The passage of macromolecules across the glomerular capillary wall is inversely proportional to their size. In addition to the size barrier, the glomerular capillary wall also contains negative charges, because of presence

of heparan sulphate proteoglycans. The negative charges repel negatively charged macromolecules, such as albumin (molecular weight 60,000 daltons).^{3,4} Most inflammatory glomerular diseases result in alteration of the size barrier and loss of anionic charges, leading to proteinuria. Low molecular weight proteins (molecular weight less than 60,000 daltons) are freely filtered through the glomerulus and are subsequently absorbed and catabolized by the proximal tubule. They include beta 2 microglobulin, retinol binding protein, alpha 1 microglobulin, and hormones such as vasopressin, insulin and parathyroid hormone.^{5,6} Injury to the proximal tubular epithelium leads to inability of the tubule to reabsorb low molecular weight proteins and to their loss in urine.⁵

Hemodynamic alterations in glomerular blood flow can also result in proteinuria. A decreased glomerular blood flow increases albumin penetration of the glomerular barrier and entry of albumin into the urinary space. This effect is functional and not pathological since restoration of blood flow promptly restores the leaky state of the glomerular capillary wall. A reduced number of functioning nephrons, as occurs in chronic kidney disease leads to increased filtration of proteins in remaining nephrons and to proteinuria. Other conditions that cause proteinuria by altering glomerular hemodynamics⁷ include exercise, fever, seizures, epinephrine use and emotional stress. Overflow proteinuria occurs when the plasma concentration of certain small proteins exceeds the capacity of the tubules to reabsorb the filtered protein, examples include presence of immunoglobulin light chains in the urine in multiple myeloma, hemoglobinuria in intravascular hemolysis, myoglobinuria in rhabdomyolysis and amylasuria in acute pancreatitis.⁸

The positive reaction to protein associated with hematuria is due to plasma albumin that accompanies the red blood cells into the urine. However, high grades of proteinuria detected in dipstick testing of grossly bloody urine

should not be ignored because the finding may reflect an underlying glomerulopathy.

MEASUREMENT OF PROTEINURIA

Qualitative Methods

The dipstick method provides an estimate of urinary protein concentration and is widely used. Proteins in solution cause a change in the color of a reagent strip impregnated with tetrabromophenol blue. Because tetrabromophenol is a pH indicator, the dipstick is buffered to prevent the influence of normal variations in urine pH on color change. False-positive results can be obtained when the urine is alkaline (pH greater than 7) or when it contains large amounts of mucus, blood, pus, semen or vaginal secretions. False-positive results can also occur in the presence of radiographic contrast material and in samples from children receiving high dosages of penicillin, cephalosporins or sulfonamides. The strips react preferentially with albumin and are relatively insensitive to other proteins such as gamma globulins. The amount of protein in the urine is assessed as 1+ (30 mg per dL), 2+ (100 mg per dL), 3+ (300 mg per dL) or 4+ (1,000 mg per dL). It is common practice in many hospital laboratories to verify the results of a positive dipstick test using sulfosalicylic acid test. In this test, three drops of a 20 percent solution of sulfosalicylic acid are added to 5 mL of urine to cause acidic pH and precipitation of proteins. The turbidity of the urine is noted by visual inspection. This test is more accurate than the dipstick method because all classes of proteins are detected. Because both dipstick and sulfosalicylic acid tests are sensitive to the concentration of protein in the urine, they can underestimate proteinuria or give false-negative results in the presence of a dilute urine (i.e. specific gravity less than 1.010). Urine with a specific gravity greater than 1.015 is necessary for reliable results.

Quantitative Methods

Several colorimetric laboratory methods are available to quantitate protein concentration in urine.⁹ Urinary protein electrophoresis and direct measurements of low-molecular-weight proteins such as β_2 microglobulin may be performed in special circumstances but are not part of the routine evaluation of a child with proteinuria. In adults, a protein excretion of less than 150 mg per 24 hours is considered normal. In children, however, physiologic proteinuria varies with age and the size of the child (Table 1). After the first year of life, daily protein excretion in children, expressed in mg/m²/24 hours, is relatively constant. The traditional way of quantitating urinary protein excretion has been to measure protein in a urine sample collected over a 12 or 24-hour period.

The patient is instructed to void after waking up in the morning and to discard that first urine and mark the time. The urine from each subsequent voiding is then collected

Table 1: Normal urinary protein excretion in infants and children

Age group	Total protein (mg per 24 hours)	Total protein (mg per m ² per 24 hours)
5 to 30 days (premature)	29	182
7 to 30 days (full term)	32	145
2 to 12 months (infant)	38	109
2 to 4 years (child)	49	91
4 to 10 years	71	85
10 to 16 years	83	63

for the next 24 hours; the final urine sample is to be voided precisely 24 hours after the timed collection had begun. Timed urine collections are difficult in young children and impossible in infants without subjecting them to bladder catheterization.

Determining the amount of excreted creatinine in the same 24-hour urine sample may be helpful in evaluating the accuracy of the collection. Steady-state daily creatinine excretion is 20 mg/kg in children from one to 12 years of age and 22 to 25 mg/kg in older children, with the lower value corresponding with creatinine excretion in girls.

A strong correlation has been found between the urine protein-to-creatinine ratio (UPr/Cr),¹⁰ obtained in random urine samples, and the 24-hour urinary protein excretion, corrected for body-surface area. Other studies have confirmed this observation.¹¹ The usefulness of urinary protein-to-creatinine ratios has been documented in normal children¹² and in children with renal disease.¹³

In adults and children over two years of age, a UPr/Cr of less than 0.2 on a random urine specimen is considered normal. In children aged six months to two years, the upper limit of normal should be extended to 0.512. A UPr/Cr above 2.0 is consistent with nephrotic-range proteinuria.

The ratio is not valid in children with severe malnutrition, as serum and urine concentrations of creatinine depends on muscle mass. In the presence of significant reductions in the glomerular filtration rate, tubular secretion of creatinine increases, and this may result in artificially low UPr/Cr values. The UPr/Cr ratio is considered by some investigators to be more reliable than 24-hour urinary protein measurements. A collection error was found in 57 percent of 24-hour urine samples, as assessed by high or low urinary creatinine content. The actual 24-hour protein excretion can be calculated from the UPr/Cr ratio at all levels of proteinuria, using a formula derived by log-log regression analysis.¹³

$$\text{Total urine protein (g/m}^2\text{/day)} = 0.63 \times (\text{UPr/Cr})$$

This method avoids the need for urine collection, and the results are obtained more expeditiously. Serial UPr/Cr ratios can be obtained over time to monitor the progression of proteinuria.

PREVALENCE OF PROTEINURIA

The prevalence of isolated asymptomatic proteinuria in children has been estimated to be between 0.6 to 6.3 percent.¹⁴⁻¹⁷ Proteinuria is usually transient and intermittent, so that much higher prevalence is observed when a single urine specimen is tested. Most children who test positive for proteinuria on initial evaluation lose the proteinuria at follow up, and only about 10 percent of the children have persistent proteinuria after 6 to 12 months.

ETIOLOGY OF PROTEINURIA

Transient or functional proteinuria: As many as 30 to 50 percent of children with proteinuria may have transient non-repetitive proteinuria⁶. Transient proteinuria can occur with strenuous exercise, emotional stress, exposure to extreme cold, epinephrine administration, abdominal surgery or congestive heart failure. It is also known to occur during febrile illnesses and after seizures. In all these circumstances proteinuria resolves spontaneously after the cessation of causal factor and an extensive workup is usually not recommended.

Intermittent proteinuria: Intermittent proteinuria indicates that protein is detectable in only some of the urine samples. This form of proteinuria may be related to posture (postural proteinuria). Some of the factors known to be associated with intermittent proteinuria are shown in (Table 2).

Persistent proteinuria: Persistent proteinuria indicates that protein is found in every urine sample. If these patients have associated evidence of renal disease such as microscopic hematuria, there are very high chances of having significant pathology in the urinary tract. Such patients should be identified and thorough diagnostic evaluation should be undertaken.

Causes of persistent proteinuria: In vast majority of cases persistent proteinuria is of glomerular origin. However, non-glomerular mechanisms can cause proteinuria too. Thus, proteinuria can be classified according to the pathophysiological mechanism responsible as shown in (Table 2).

Glomerular Mechanisms

Any disease, which damages the glomerular basement membrane, increases glomerular permeability to plasma proteins results in proteinuria. The whole of increased filtered load of proteins cannot be reabsorbed and the majority will appear in the urine. Acute and chronic glomerulonephritis are thought to produce proteinuria by this mechanism. These diseases cause severe histological damage to the glomeruli including abnormalities in the glomerular basement membrane. Such injury increases the effective pore size in the glomeruli. This increases the permeability of the mechanical barrier to the filtration of proteins and permits an increase, not only in the filtration of albumin but also of larger proteins such as globulin.

A second major mechanism for glomerular proteinuria is loss or reduction of the glomerular charge barriers and this results primarily in albuminuria. There is little or no increase in glomerular permeability to globulins, so this proteinuria is highly selective. The classical cause for this kind of proteinuria is minimal change nephrotic syndrome (MCNS).

A reduction in nephron mass results in increased glomerular permeability and increased proteinuria from the residual nephrons. This mechanism is responsible for proteinuria in renal transplant donors and in patients of cystic kidney disease.

Any increase in filtration fraction will increase plasma protein concentrations at the distal end of the glomerular capillaries to a level above the threshold. This explains the proteinuria due to stress and that associated with high levels of angiotensin.

Nonglomerular Mechanisms

The proximal convoluted tubule mainly reabsorbs most of the filtered protein and any damage to this segment of the nephron can result in proteinuria. Causes of tubular proteinuria are shown in (Table 2).

Overflow proteinuria results when the plasma level of a protein exceeds the renal threshold of that protein.

Table 2: Causes of proteinuria classified by type and mechanism

Intermittent proteinuria

- Postural
- Nonpostural
 - Contamination of urine
 - False positive (penicillin, radio contrast agent, sulfonamide administration)
 - Nonrenal cause, e.g. fever, exercise
 - Obstruction of urinary tract

Persistent proteinuria

- Glomerular causes
- Damage to glomerular basement membrane, e.g. acute and chronic glomerulonephritis
- Loss of glomerular polyanion, e.g. minimal change nephrotic syndrome
- Increased permeability in residual nephrons, e.g. end stage renal disease
- Hemodynamic alterations, e.g. hyperreninemia and early stages of diabetes
- Cause unknown, e.g. asymptomatic proteinuria

Nonglomerular causes

- Decreased tubular reabsorption—Fanconi's syndrome
- Overflow proteinuria
- Normal renal function—repeated albumin transfusions, myeloma or macroglobulinemia
- Decreased renal threshold—albumin infusions in nephrotic syndrome
- Secretory proteinuria—Tamm-Horsfall proteinuria, analgesic nephropathy

This can occur even when the kidney function is normal. Plasma concentration of albumin may increase sufficiently to cause proteinuria after repeated transfusions of either albumin or whole blood. Alternatively in multiple myeloma the appearance in the plasma of Bence Jones protein will result in loss of this protein in the urine and hence, clinically detectable proteinuria. Similarly, the release of free hemoglobin into the plasma causes the rapid appearance of this protein in the urine.

The increased excretion of tissue proteins into the urine may result in proteinuria too and is referred to as secretory proteinuria. Some of the proteinuria observed with renal stones and urinary tract infection may result from irritation of the lower urinary tract and the increase of tissue proteins.

Orthostatic (Postural Proteinuria)

The presence of increased amounts of proteins in urine formed when the patient is in upright position, but not in the urine formed when the patient is supine is referred to as postural proteinuria. In only 15 percent of the cases the postural proteinuria is fixed and reproducible, in remaining patients it is referred to as variable since not every orthostatic challenge results in proteinuria. It accounts for up to 60 percent of all cases of asymptomatic proteinuria¹⁸ reported in children. If all laboratory tests are normal except for persistently elevated protein excretion the possibility of postural proteinuria should be considered, this is best done by using the so-called orthostatic test. The patient is instructed to urinate just before going to bed at night and to discard the urine. He or she must remain supine all night and urinate the next morning immediately after arising. This urine sample is kept separate and labeled 'supine' or 'recumbent.' Additional urine samples are then collected and pooled during the next 12 to 16 hours, while the patient maintains normal daily activity. The final sample should preferably be collected in the evening, just before the patient goes to bed; this pooled sample should be labeled as 'active' urine. The duration of collection time for the latter sample can be shortened to 12 hours or less. In patients with orthostatic proteinuria, the supine sample will be free of protein, but the active sample will contain protein.⁸

Children with orthostatic proteinuria excrete less than 1 g of protein in 24 hours (UPr/Cr less than 1.0). The long-term prognosis for young adults with orthostatic proteinuria is excellent, even after 20 years of follow-up,^{19,20} but similar data is not available for children. However, it is believed that the prognosis in children and adolescents is equally good. Long-term follow up is necessary (unless proteinuria resolves) in order to monitor the child for evidence of renal disease (hematuria, hypertension, diminished renal function or proteinuria exceeding 1 gm/day).²¹ Yearly follow-up is recommended for children diagnosed with this condition.

EVALUATION OF A PATIENT OF PROTEINURIA

A positive dipstick for protein on random analysis is common in children. General screening of normal school age children with a urine dipstick (proteinuria >1+) will be seen in 5 to 10 percent. However, only 0.1 percent of children have persistent proteinuria.

In evaluation it is important to exclude false positive cases (Common causes for false positive results are shown in [Table 3]).

If the test is found to be positive due to these reasons then a repeat test should be done and shown to be negative.

Further evaluation of proteinuria should include a complete history, including a family history of renal disease, recent upper respiratory infections, gross hematuria, changes in weight and changes in urine output. The physical examination should include measurements of height, weight and blood pressure, identification of edema, ascites, skin pallor and palpation of the kidneys in newborn infants. A urinalysis should be performed and blood obtained for determination of electrolytes, blood urea nitrogen, creatinine, total protein and albumin levels, as well as a complete blood cell count and C3 complement level. A quantitative assessment of urinary protein excretion should be made, using either a 24-hour collection or a random urine sample for the UPr/Cr ratio. Clinical correlations for proteinuria have been listed in (Table 4).

A good clinical history, examination, and investigations are required to determine whether proteinuria is transient, orthostatic or persistent in type. Transient proteinuria, which is often associated with fever, stress, dehydration or exercise is not considered to be indicative of underlying renal disease.²²

Table 3: Causes for misleading screening tests for proteinuria

False positive results

- Dipstick method
 - Highly concentrated urine
 - Alkaline urine (ph > 8)
 - Gross hematuria, pyuria, bacteriuria
 - Dipstick left in urine too long
 - Contamination and drugs:
 - Antiseptics, chlorhexidine, benzalkonium
 - Phenazopyridine

Protein precipitation methods

- Highly concentrated urine
- Gross hematuria, pyuria, bacteriuria
- Drugs
 - Radiocontrast agents
 - Penicillin, cephalosporin
 - Metabolites of tolbutamide and sulfonamide

False negative results

- Very dilute urine
- Acidic urine (pH 4.5)
- Nonalbumin proteinuria

Table 4: Clinical correlations for proteinuria

<i>Likely diagnosis</i>	<i>History/physical examination</i>	<i>Creatinine</i>	<i>Albumin</i>	<i>C3 complement</i>	<i>UPr/Cr</i>	<i>Other associations</i>
Orthostatic proteinuria	>10 years of age	Normal	Normal	Normal	<1.0	–
Minimal change disease	Edema <6 years of age	Normal	Low	Normal	>2.0	Increased cholesterol
Acute glomerulonephritis	Edema, gross hematuria	Normal or high	Normal or low	Low	<1.0	Increased ASO titer
FSGS, MGN, MPGN	BP normal or high	Normal or high	Normal or low	Normal or low	<1.0	Hematuria
Henoch-Schönlein purpura nephritis	Purpuric rash on thigh and buttocks	Normal	Normal or low	Normal	Variable	Hematuria
Lupus nephritis	Butterfly rash, arthritis	Normal or high	Normal or low	Low	Variable	Increased ANA, hematuria
Tubulointerstitial disease	UTIs, polyuria	Normal or high	Normal	Normal	<1.0	–

If orthostatic proteinuria is diagnosed, the child should be followed with annual visits, including determination of a UPr/Cr ratio. If fixed isolated proteinuria is ascertained, the workup depends on the degree of proteinuria. If total protein excretion is less than 1 g per 24 hours (or the UPr/Cr is less than 1.0), twice-yearly visits, later extended to annual visits, with determination of the UPr/Cr ratio are sufficient. If proteinuria persists beyond one year, renal biopsy should be considered. If the total protein excretion is more than 1 g per 24 hours (or the UPr/Cr is greater than 1.0), a urinalysis should be performed and blood obtained for determination of electrolytes, blood urea, creatinine, total protein and albumin levels, C3 complement level and a complete blood cell count.

In young children (under six years of age), renal ultrasonography may be helpful to detect anatomic or congenital abnormalities such as polycystic kidneys. If the laboratory test results are abnormal, for example, if the patient has increased creatinine levels or hypocomplementemia or hematuria, a chronic glomerular disease may be present. Renal biopsy is indicated in these patients, and referral to a pediatric nephrologist is recommended.

The existence of an antecedent streptococcal infection may be investigated by measuring antistreptolysin-O and anti-deoxyribonuclease B titers. Postinfectious glomerulonephritis is usually self-limited, and a renal biopsy is not indicated. However, except in very mild cases, the patient should be referred to a pediatric nephrologist. If urinary protein excretion is in the nephrotic range (UPr/Cr greater than 2.0), even in the absence of edema and the patient is younger than six years of age, idiopathic nephrotic syndrome is likely, and a trial of corticosteroid therapy is warranted.

Renal biopsy is not indicated unless the patient has other abnormal laboratory test results, such as hematuria,

increased blood urea nitrogen and creatinine levels or hypocomplementemia. If urinary protein excretion is in the nephrotic range and the patient is older than six years of age, idiopathic nephrotic syndrome is less likely, and referral to a pediatric nephrologist is recommended. Renal biopsy will identify the type of glomerular disease responsible for the nephrotic syndrome (Table 2).

TREATMENT CONSIDERATIONS

Proteinuria is a marker of parenchymal injury in kidney disorders of diverse etiologies. Primary treatment of most disorders by immunomodulator medications is empiric. Treatment aimed at the mechanism of disorder, often immune mediated, also treats proteinuria.

Excessive restrictions on the child's lifestyle and physical activity are not necessary. Dietary protein supplementation to replace the loss of protein is not recommended and may be harmful. Most children with protein excretion under 1 g per 24 hours do not develop edema. Avoiding excessive salt intake is desirable, and more rigorous salt restriction may be necessary if edema develops. Therapy with an angiotensin converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB) can bring about a significant reduction of proteinuria.²³ The antiproteinuric effect appears to be connected to their diverse effects including control of hypertension. The explanation for the mechanism of anti-proteinuric effect is selective vasodilatation of the efferent arteriole which lowers the filtration pressure and hence the amount of protein in the ultrafiltrate. The use of ACE inhibitors in the treatment of renal disease may cause a reduction in glomerular filtration rate and hyperkalemia and therefore, if ACE inhibitors are used, renal function should be closely followed with periodic measurement of blood urea nitrogen, creatinine and potassium levels.

PROGNOSIS

While patients with orthostatic proteinuria have an excellent prognosis, the long-term prognosis for children with isolated fixed proteinuria remains unknown. It is generally believed that children with isolated proteinuria not exceeding 1 g per 24 hours have a better prognosis than those with higher amounts of protein in their urine. In a six-year retrospective study of 31 children with proteinuria of 10 months duration, renal biopsies were performed in 17 children.²⁴ Of these children, 12 had pathologic findings on biopsy, including eight with focal and segmental glomerulosclerosis. Among 12 of the 14 patients who were not biopsied and four of the five patients with normal histology, proteinuria completely resolved.

In a study²⁵ of 53 Japanese children with asymptomatic proteinuria, significant glomerular changes were observed on renal biopsy in 25 patients (47 percent). Fifteen of them had focal glomerulosclerosis. Seven patients with abnormal glomerular histology developed renal insufficiency; none of the patients with normal glomerular histology developed renal insufficiency. In a survey of pediatric nephrologists,²⁶ 36 percent of the physicians surveyed would perform a renal biopsy in a nine-year-old child with moderate proteinuria (600 mg per day). Until more information is available, the decision to perform a renal biopsy in a child with isolated proteinuria will depend on factors such as parental or physician anxiety and the availability of effective therapy.

Routine antenatal ultrasonography has focused our attention to urological abnormalities that occur in babies. This review aims to outline a logical approach to this problem through the gestational period into the neonatal period emphasizing what needs to be done and when; and, more importantly, what need not be done.

What is the Magnitude of the Problem?

It is estimated that some degree of dilatation of the fetal renal collecting system is identified in 1 to 5 percent of all pregnancies,¹ but in only one-fifth of these is the dilatation significant.² It must be understood at the outset that the term hydronephrosis simply denotes dilatation of the upper urinary tract and does not necessarily imply the presence of an obstructive lesion or a significant functional abnormality of any kind. In fact, only 3 percent of babies with a renal pelvis diameter <10 mm had a significant abnormality needing surgery. The usual causes of antenatal hydronephrosis include:

- *Functional dilatation:* Minor degree of dilatation that usually spontaneously resolves later in gestation or early infancy.
- *Obstruction:* Usually at the pelviureteric junction, at the ureterovesical junction, or in the urethra (as in posterior urethral valves)
- Vesicoureteral reflux
- Renal dysplasia including multicystic dysplastic kidneys
- Uncommon conditions like duplex collecting system or Prune-belly syndrome, etc.

What is Significant Dilatation?

In order to standardize data, the Society of Fetal Urology (SFU) has adopted a grading system for hydronephrosis (Table 1).¹ An alternate method is to measure the renal pelvis anteroposterior diameter.^{3,4}

A renal pelvis anteroposterior (AP) diameter of >10 mm after 24 to 26 weeks of gestation is generally accepted as a reasonable criteria to denote significant dilatation.^{3,5} The presence of caliectasis or calyceal dilatation is considered an additional factor indicative of significant hydronephrosis.^{1,6} More recently, there is evidence to suggest that milder degrees of dilatation may also be significant in that such babies may have vesicoureteral reflux (VUR) rather than obstruction.⁷⁻⁹ Currently, a renal pelvis diameter of at least 4 mm before 33 weeks and 7 mm after 33 weeks is considered significant.¹⁰ Antenatal hydronephrosis can be classified as mild, moderate or severe for prognostic purposes (Table 2).¹ A large systematic review suggests that the risk of significant postnatal pathology is 11.9 percent for mild, 45.1 percent for moderate and 88.3 percent for severe hydronephrosis.¹¹

Table 1: Grading of hydronephrosis¹

Grade	Pattern of renal sinus splitting
0	No splitting
1	Urine in pelvis barely splits sinus
2	Urine fills intrarenal pelvis
2	Urine fills extrarenal pelvis, major calyces dilated
3	SFU Grade 2 and minor calyces dilated and parenchyma preserved
4	SFU Grade 3 and parenchyma thin

Table 2: Definition of antenatal hydronephrosis (ANH) by anteroposterior diameter¹

Degree of ANH	Second trimester	Third trimester
Mild	4 to <7 mm	7 to <9 mm
Moderate	7 to <10 mm	9 to <15 mm
Severe	>10 mm	>15 mm

What Information is Sought on an Antenatal Ultrasound Scan?

While assessing the significance of the antenatal renal dilatation, particularly with a view to identifying a possible cause and whether it is worth continuing pregnancy, the US must be done carefully and must give the following information:

- Estimated fetal size and weight, and its comparison with normal for that gestational age
- Amniotic fluid volume (AFV)
- Whether dilatation is unilateral or bilateral, and whether ureters are dilated or not
- Degree of dilatation (SFU grading) and dilatation of calyces
- Bladder fullness, thickness and emptying
- Appearance of external genitalia
- Any other associated malformation.

The initial study is usually done at 16 to 20 weeks gestation using a 5 MHz transducer. There are no specific guidelines on how frequently to image the fetus. It would be reasonable to do the US every 4 weeks till 32 weeks and two weekly thereafter, mainly to assess the AFV.

What is the Current Status of Fetal Intervention?

The rationale for fetal urinary decompression is that those with severe obstruction early in gestation have significant impairment of both renal and pulmonary development. It has been recognized that if the AFV is adequate up to 27 weeks gestation, then severe pulmonary hypoplasia is unlikely to occur.¹² Percutaneous shunting of the bladder into the amniotic space is technically feasible with some morbidity. However, its role is extremely limited.

There is no place for any fetal intervention in unilateral hydronephrosis. Even with bilateral pelviureteric junction obstruction (PUJO), if the AFV is normal, percutaneous drainage of the fetal kidneys or early delivery are not warranted. For babies with posterior urethral valves (PUV), poor prognostic criteria include:

- Early severe oligohydramnios
- Renal cortical cysts suggesting renal dysplasia
- Bladder urine with sodium >100 mEq/L, chloride >90 mEq/L, osmolality >210 mOsm/L, increased β_2 -microglobulin
- Evidence of pulmonary hypoplasia.

What is the Natural History of Antenatal Hydronephrosis?

Spontaneous resolution of prenatally detected hydronephrosis occurs in 50 to 70 percent of all fetuses. This regression may be noted on serial antenatal ultrasound scans or in the postnatal life up to 3 years.^{3,13-17} Furthermore, in a substantial number, even if the hydronephrosis does not resolve completely, the renal function does not deteriorate despite persistence of pelvic dilatation.¹⁶ On

the other hand, 15 to 33 percent of patients show progressive renal deterioration during observation.¹⁸⁻²⁰ It has been noted that increasing degrees of hydronephrosis correlated with increased risk of urological pathologies that may need surgical intervention.^{21,22}

Postnatal Evaluation of Antenatal Hydronephrosis

Immediately after birth, the following must be recorded:

- Sex of the baby; in males PUV is an important diagnosis to be considered, requiring early intervention
- Palpable kidney—common causes are PUJO (more commonly unilateral), multicystic dysplastic kidney (unilateral), PUV (unilateral or bilateral)
- Palpable bladder—indicative of PUV in boys.

If the diagnosis of PUV is suspected, all further investigations need to be done urgently as the baby requires early surgical intervention. These babies need renal function tests, US scan, voiding cystourethrogram (VCUG) within a day or two after birth so that surgical ablation of the valves may be done at the earliest.

In all other situations, there is no great haste to perform investigations. The initial study to be done is the US scan that must preferably not be done in the first 2 to 3 days. However, if the mother is being discharged earlier, it is practical to send the baby with the US scan results.

Following the US scan, a VCUG is done. There is no doubt that the conventional VCUG is preferred to a direct radionuclide cystogram (DRCG) because the latter does not give a good delineation of the bladder and urethral anatomy and that reflux, if present, cannot be accurately graded. Controversy surrounds two aspects of VCUG:

- Should VCUG be done in all babies?
- When should it be done?

Should VCUG be Done in all Babies?

VCUG is an invasive procedure, and some studies have quoted a 6 percent rate of UTI following VCUG. This has made most clinicians reluctant to ask for a VCUG in newborn babies. However, if properly performed under antibiotic cover, the procedure is safe with no risk of UTI (personal experience²³). There are some recent reports that claim that routine VCUGs may not be indicated in all babies with antenatally detected hydronephrosis.²⁴⁻²⁸ These studies recommend VCUG for those babies with:

- Bilateral hydronephrosis
- Dilated ureters
- Presence of UTI.

This literature against routine use of VCUG is far from convincing. Most large centres recommend that this test must be done in all babies with antenatal hydronephrosis even if the postnatal US scan is normal.^{1,4,29} VUR has been recorded in 15 to 30 percent babies born with an antenatal diagnosis of hydronephrosis.^{4,11,30} Tibballs³¹ reported that among 255 renal units with reflux, the postnatal US

was normal in 177 (70%). Furthermore, some studies have shown that the postnatal US may be normal even with the higher grades of VUR (12% of grade V and 31 percent with grade IV).³²⁻³⁴

When Should it be Done?

Some authors recommend that a VCUG should be done at 4 to 6 weeks postnatal age. Though, again, it would be more practical to do it before the baby leaves hospital. Either way, till the VCUG has been done and VUR excluded the baby needs to be on low dose antibiotics using amoxycillin (15 mg/kg/day) or cephalexin (50 mg/kg/day). Trimethoprim (2 mg/kg/day) may be used safely in babies after 4 to 6 weeks of age. Neonates who do not have VUR do not need further antibiotic chemoprophylaxis.

When is a Radionuclide Study Indicated?

In most babies, the US scan is repeated at 4 to 6 weeks of age. In most situations, a diuretic renogram is done at about 4 weeks of age to evaluate renal functional status and presence of obstruction. Renograms performed immediately after birth may be difficult to interpret due to the immature function of the kidneys and their handling of the radioisotope. Diuretic renogram is indicated in all kidneys with grade 3 or 4, and occasionally grade 2 hydronephrosis;^{35,36} there is bilateral PUJ or ureterovesical junction obstruction; if there is a solitary kidney; or the kidney is palpable and tense.

The renal scan is superior to the IVP for many reasons. It is safer (contrast reactions and radiation are less), there is better visualization of the collecting system and, objective and quantitative assessment of relative function of each kidney is possible. The ideal radionuclide is MAG3, but a cheaper, though less accurate option is the DTPA (not DMSA) scan. In lower grades of hydronephrosis, if VUR has been excluded no further workup with renal scans may be necessary. These babies need observation with 3-monthly ultrasounds to ensure that the degree of hydronephrosis is static and not worsening.

Follow-up Evaluation

Currently, no single test can reliably predict whether a hydronephrotic kidney will improve or deteriorate. Most people agree that nearly all infants with unilateral PUJ obstruction are initially managed conservatively if the diuretic renogram shows at least 35 to 40 percent differential renal function.^{35,37} Exception are infants with renal infection, tense renal lump,^{35,36} or pelvis AP diameter >50 mm.²⁰ Follow-up US scan and diuretic renography is repeated at 3 to 6 months and if there is a deterioration in differential renal function, pyeloplasty is indicated.^{18-20,35} Nearly 20 percent infants will show deterioration on follow-up requiring pyeloplasty. This usually happens in the first year of life.^{16,18,19}

Children with lesser degree of hydronephrosis (up to pelvis AP diameter of <20 mm) need to be followed up with an US scan at 3 m, 1 year; then 2, 5, and 10 years. Radionuclide study is done at 3 m, 1 year and if required at 2, 5, and 10 years. If the renal function or degree of dilatation improves, there is no further need for the isotope study.²⁰

Vesicoureteral Reflux in Neonates

VUR may be seen in 20 to 35 percent neonates with antenatal hydronephrosis.^{1,29,38-41} Nearly 80 percent of such patients are boys. The presence of a large, thin walled bladder, normal renal architecture and AFV in a male fetus most likely signifies massive VUR designated as megacystis-megaureter syndrome.⁴² Neonates with reflux should undergo a baseline DMSA renal scan, (not DTPA) to identify scarring, which may be present in 40 percent cases.³⁵

Most such neonates are initially managed medically with antibiotic prophylaxis (initially amoxycillin or cephalexin for 2 months, later trimethoprim or nitrofurantoin). Circumcision may be recommended in these boys to reduce the risk of UTI.

Urine examinations are indicated if the baby is febrile, not feeding well, sluggish, not gaining weight or having loose stools. Follow-up is done with US scan, which is repeated at 3 m, 6 m, and 1 year. VCUG, but if available a radionuclide cystogram (DRCG), is preferred at 1 year and 2 years to reevaluate the status of reflux. If two consecutive studies show absence of VUR, antibiotic prophylaxis may be discontinued.

Surgery for the correction of reflux may be indicated in babies who have breakthrough UTI or progression of renal scarring.

Posterior Urethral Valves

PUV is the most common cause of severe obstructive uropathy in neonates. It presents as a spectrum of clinical manifestations. On the one hand, there may be a neonate who voids near-normally, the bladder may be empty, renal function is normal, yet the only evidence is bilateral hydroureteronephrosis. The other end of the spectrum is a preterm baby with severely deranged renal function and acidosis, evidence of pulmonary hypoplasia with severe obstructive uropathy. Approximately one-third of all babies born with PUV finally develop chronic renal insufficiency. Prognosis is worse when the prenatal US detected the anomaly prior to 24 weeks gestation. Favorable prognostic criteria include:

- S. creatinine that falls to below 1 mg/dl after bladder decompression
- Unilateral reflux into a nonfunctioning kidney (the "pop-off" effect) with normal contralateral kidney
- Urinary ascites (this results in natural decompression)
- Maintenance of corticomedullary differentiation on renal US.

The initial treatment of such babies is bladder decompression using a fine infant feeding tube and biochemical stabilization. Following bladder decompression, these babies pass large volumes of urine and lose a lot of electrolytes in the urine. Both, volume and electrolytes need to be adequately replaced. A VCUG must be done immediately. Frequent catheter changes are a potent source of urosepsis that can be disastrous in these critically balanced babies.

Definitive treatment in the form of endoscopic transurethral valve ablation is usually possible in most neonates and must be done at the earliest. In case the equipment is not available or does not negotiate the urethra, a poor second choice is a vesicostomy. Vesicostomy may also be indicated if the s. creatinine levels remain very high after valve ablation or there is persistent infection. In the current scenario, supravescical diversion in the form of cutaneous pyelostomy or ureterostomy is rarely necessary.

Management of Difficult Nephrotic Syndrome

PK Pruthi, Kanav Anand

BACKGROUND

Nephrotic syndrome is a renal disease which occurs due to increased permeability across the glomerular filtration barrier. It is classically characterized by proteinuria (>1 gm/m²/day), hypoalbuminemia (<2.5 gm/dl), edema and hyperlipidemia (serum cholesterol >200 mg/dl).¹⁻⁴ Proteinuria sets in motion, a series of homeostatic and compensatory mechanisms that result in clinical features of nephrotic syndrome.^{1,2}

Management of nephrotic syndrome focuses on:

- Treatment of the causative disease (minimal change nephrotic syndrome (MCNS), focal segmental glomerulosclerosis (FSGS), membranoproliferative glomerulonephritis (MPGN) and membranous glomerulonephritis) with steroids or other immunosuppressive agents.
- Treatment of complications of nephrotic syndrome.

In treatment of nephrotic syndrome difficulties may be encountered in either of these two management issues.

DIFFICULTY IN MANAGEMENT OF CAUSATIVE DISEASE

Frequent Relapser or Steroid Dependent Nephrotic Syndrome (SDNS)

Patients having frequent relapses or those who are steroid dependant require repeated courses of prednisolone and often develop steroid toxicity. Important side effects include development of severe cushingoid features, hirsutism, hypertension, impaired glucose tolerance, posterior subcapsular cataract, growth retardation and emotional problems.⁵ Serious complications of steroid toxicity should not be allowed to develop in such cases. Following treatment of relapse, the dose of prednisolone is tapered gradually to maintain the patient in a state of remission on alternate day dose of

0.5 to 0.7 mg/kg or lower. Alternate day prednisolone may be administered for 9 to 18 months.⁶ A close monitoring of growth, blood pressure and evaluation for features of steroid toxicity is essential. If the prednisolone threshold to maintain remission is higher or there is development of steroid toxicity then the following immunosuppressive agents are recommended. Instead of prednisolone, deflazacort can also be used as an alternative in view of its much better side effect profile.⁷

Levamisole⁶⁻⁹

Levamisole is an immunomodulatory agent without any anti-inflammatory effect and has been successfully employed in patients with frequent relapses and steroid dependence. This can be administered in a dose of 2 to 2.5 mg/kg on alternate days for 12 to 24 months or even longer. It has been found to be effective in about 50 to 60 percent of cases with a marked reduction in the relapse rate. This drug acts as a steroid sparing agent. Treatment with prednisolone in a dose of 1.5 mg/kg on alternate days is continued and gradually reduced by 0.15 to 0.25 mg/kg every 4 weeks to a maintenance dose of 0.25 mg/kg, which may be continued for 6 months. In 20 to 30 percent of cases prednisolone can be stopped and levamisole alone is sufficient. There is a strong tendency for relapse to recur when levamisole is discontinued. The chief side effects of treatment with levamisole are leucopenia, flu like symptoms and skin rash. Total count should be monitored every 4 to 8 weeks. The reduction in neutrophils is usually transient and reversible on withdrawal of the drug.

Alkylating Agents¹⁰⁻¹²

Alkylating agents chiefly cyclophosphamide may induce long lasting or rarely permanent remission in children with frequent relapsing or steroid dependent nephrotic

syndrome. This drug is administered after inducing remission with standard prednisolone treatment. Cyclophosphamide (CMP) may be administered orally in a dose of 2 mg/kg along with alternate day prednisolone as 1-1.5 mg/kg for 12 weeks. This results in a prolonged remission in majority of cases. The results are better in older children. Only a single course of the drug is usually recommended. Total leucocyte count needs to be monitored every 2 weeks. Treatment is discontinued if the total counts falls below 4000 mm³. Gonadal toxicity is an important consideration with pubertal and post pubertal patients being most vulnerable, especially the male sex. Hemorrhagic cystitis is an uncommon complication and increasing fluid intake and frequent voiding help in preventing this. Treatment with CMP may rarely cause alopecia, nausea or vomiting. A standard course of cyclophosphamide up to a cumulative dose of 168 mg/kg is reasonably safe. CMP may also be used as monthly pulses for six months, but it is unclear whether intravenous cyclophosphamide is as effective as oral cyclophosphamide in sustaining remission. One study, for example, reported that intravenous cyclophosphamide was not effective in preventing relapse in steroid-dependent patients.¹³ In contrast, a randomized trial of 47 patients found that the risk of relapse at six months was lower with intravenous cyclophosphamide (six monthly doses) than with a 12-week course of oral cyclophosphamide, although the benefit did not persist at two year follow up.¹⁴ The use of this subset of drugs should be reserved for those patients who cannot be managed with long term low dose alternate day steroids or levamisole. Therefore, treatment with CMP may be considered in patients showing:

- a. Significant steroid toxicity.
- b. Severe relapses with hypovolemia and thrombosis.
- c. Poor compliance on follow-up.

Calcineurin Inhibitors

Cyclosporine^{11,15,16}

Cyclosporine(CsA) is a calcineurin inhibitor which acts by inhibiting the T helper cells and inhibiting the production and release of lymphokines. It is administered in a dose of 4-5 mg/kg in two divided doses for 12 to 24 months. Therapy is continued with alternate day prednisolone for 12 to 24 weeks and then tapered off gradually. Side effects such as hypertension, gum hypertrophy and hirsutism may occur in which case dose may be reduced to 3 mg/kg per day. Patients who continue to have relapses after a course of cyclophosphamide can be considered for treatment with cyclosporine. A renal biopsy is essential before starting this drug. A wider use of CsA is precluded by its nephrotoxicity. Blood levels of urea, creatinine, transaminases, cholesterol and CsA should be measured every 4-6 months. Blood levels of CsA should be kept between 100 and 150 ng/ml. It becomes essential to monitor the blood levels of CsA in patients who are nonresponders, non-compliant or who develop an elevated serum creatinine

while on treatment with this drug. Cyclosporine is recommended in patients that continue to be steroid-dependant or frequent relapser despite a course of levamisole or CMP.

Tacrolimus

It has a similar mechanism of action as cyclosporine and is administered in a dose of 0.1-0.2 mg/kg/day in two divided doses. Alternate day prednisolone is also be continued. The main advantage of tacrolimus over CsA is lack of cosmetic side effects. Tremors, blood glucose abnormalities and diarrhea are few of the common side effects. Its trough levels should be maintained between 4 and 8ng/ml.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF)¹⁷⁻¹⁹ is a potent reversible inhibitor of inosine monophosphate dehydrogenase, an enzyme required for purine synthesis. Mycophenolate mofetil (MMF) has shown benefit in reducing relapse rates and steroid requirements in patients with frequent relapses or steroid dependant cases. Long term treatment with this drug appears to be promising in patients with difficult nephrotic syndrome with no risk of nephrotoxicity, hepatotoxicity or neurotoxicity. The major side effects of this drug are gastrointestinal (abdominal pain, diarrhea) and hematological. The dose of MMF is 30 mg/kg/day (600-750 mg/m²/day) in two divided doses. It can be continued for a period of 1-2 years, while keeping a watch on the leucocyte counts and serum transaminases levels. Treatment is temporarily held if leucocyte counts fall below 4000 mm³.

Rituximab

Rituximab (RTX), a chimeric anti-CD20 monoclonal antibody, which is a drug used in treatment of rheumatoid arthritis and B cell lymphomas, has been found useful in reducing the relapse rates in children who are frequent relapsers or have steroid dependence, thus reducing the steroid usage. It is also a treatment of choice for children who are refractory to all other immunosuppressants mentioned above. It can be given as 1-2 doses of 375 mg/m² (IV infusion), at weekly intervals. The response to rituximab appears to be better if the patient is in remission at the time of the infusion. Therefore, rituximab should not be administered during a relapse but after remission has been induced by increased doses of steroids.²⁰⁻²³

Relapses during and following treatment with levamisole, CMP, CsA, tacrolimus or MMF are treated with standard regimen. The benefits of using these immunosuppressive agents should be weighed against their toxicity before initiating them.

Steroid Resistant Nephrotic Syndrome

Steroid resistance is defined as absence of remission despite therapy with daily prednisolone at a dose of 2 mg/kg/day for 4 weeks.²⁴ Such a child need to be biopsied (Table 1) and he can have any of the below mentioned

Table 1: Indications for kidney biopsy in nephrotic syndrome*At Onset*

- Age of onset <1 year
- Gross hematuria, persistent microscopic hematuria or low serum C3
- Sustained hypertension
- Renal failure not attributable to hypovolemia
- Suspected secondary causes of nephrotic syndrome

After Initial Treatment

- Proteinuria persisting despite 4-weeks of daily corticosteroid therapy
- Before treatment with cyclosporine A or tacrolimus

histological patterns on renal biopsy: minimal change nephrotic syndrome (MCNS), mesangial proliferative glomerulonephritis (MesPGN), focal segmental glomerulosclerosis (FSGS), membranoproliferative glomerulonephritis (MPGN) and membranous nephropathy.

Steroid Resistant Minimal Change Nephrotic Syndrome

A very small proportion of minimal change nephrotic syndrome (MCNS)²⁵ have initial steroid resistance. Of these almost 30 percent respond to treatment with a 12 weeks course of cyclophosphamide. Those who subsequently relapse respond to steroids. Intravenous administration of high dose methylprednisolone or dexamethasone has been used in some patients of MCNS who are oral prednisolone resistant. Cyclosporine in combination with alternate day prednisolone may induce remission in 60 to 70 percent of patients of steroid resistant MCNS. Most patients who respond, do so within 3 months of therapy. The treatment is carried out for 2 to 3 years. Tacrolimus may also be used in place of cyclosporine, in case the child develops side effects. Rituximab (anti-CD20 monoclonal antibody) may be tried in case other therapies fail.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS)²⁶⁻²⁸ is the most frequently encountered progressive glomerular disease. About 70 to 80 percent patients with focal segmental glomerulosclerosis (FSGS) will have initial or late steroid resistance. Idiopathic FSGS should be distinguished from secondary FSGS that can occur in conditions like HIV infection, reflux nephropathy, sickle cell disease and hyperfiltration injury. The initial treatment of FSGS is similar to that of MCNS. Some of the patients who give a positive response to steroids will relapse. Guidelines for treatment of this group of patients are similar to those of relapsing MCNS. A repeat course of steroids may again induce a remission if steroids were earlier given more than 6 months back. However in those who relapse earlier repeated high dose steroid therapy may result in

unacceptable cumulative toxicity. Therefore alternative forms of treatment such as CMP or CsA may be useful. In patients with glomerular tip lesion variant of FSGS, a trial of steroids is appropriate because many patients show a decline in protein excretion with steroids.

Prednisolone resistant FSGS has been successfully treated with pulse methylprednisolone. Pulse methylprednisolone has been used in a dose of 30 mg/kg three times a week for 2 weeks, once a week for 8 weeks, once in 2 weeks for another 8 weeks and then once a month for 6 to 12 months. The results of this regimen are good, demonstrating sustained remission in 60 percent of patients with steroid resistant FSGS. Some patients have also been given alkylating agents along with alternate day steroids and about 70 percent of children have shown benefit. Patients resistant to prednisolone may be induced into remission by using calcineurin inhibitors (cyclosporine/tacrolimus). A combination of CsA and prednisolone is reported to cause partial to complete remission in about 50 percent of patients. Long-term therapy with CsA may arrest progression of FSGS by reducing proteinuria. Plasmapheresis has also been used in some cases to good effect. Rituximab is nowadays being used as rescue therapy for patients who are refractory to all other drugs.

Membrano Proliferative Glomerulonephritis (MPGN)²⁵

Corticosteroids, immunosuppressive agents and anti-platelet therapy have been used with variable benefits. Early administration of relatively high doses of prednisolone (1-1.5 mg/kg) on alternate days for prolonged periods (3-5 years) may have a favorable effect in children. Patients should be screened for hepatitis B and C infection before initiating steroid therapy. Hypertension should be controlled with appropriate medications. ACE inhibitors may be a preferred class of drug as they will also help in decreasing the proteinuria.

Membranous Nephropathy

The condition is rare in children and most cases are secondary. Hepatitis B is the most frequent cause of membranous glomerulonephritis (MGN)²⁵ in children. Other causes include hepatitis C, SLE and exposure to gold, penicillamine and non-steroidal anti-inflammatory drugs. Children with hepatitis B associated MGN typically go into spontaneous remission with the development of antibodies. Such patients may be treated with lamivudine and/or other antiviral agents. In idiopathic MGN with persistent nephrotic syndrome, prednisolone and alkylating agents or calcineurin inhibitors may be judiciously used.

MANAGEMENT OF COMPLICATIONS**Edema**

Early treatment of relapse and judicious use of diuretics will ensure that the child does not develop massive

edema. Furosemide and bumetanide are very potent diuretics. These loop diuretics are organic anions mostly bound to plasma protein and very little of the diuretic reaches tubules through glomerular filtration. They are secreted into the lumen of the proximal tubule by the organic anion transport system and act on the luminal side of thick ascending limb of loop of henle. Patients with massive edema are usually resistant to the action of these diuretics.²⁹⁻³¹ In such cases up to 70 percent of the drug within the tubular lumen may be bound to the filtered protein and large doses of loop diuretics may be required. Mild edema can be treated with salt restriction (2 mEq/kg/ day). For more significant edema furosemide 1-3 mg/kg is used in 2 to 3 divided doses. Occasionally continuous intravenous infusion of furosemide as 4-10 mg/kg over 24 hours may be necessary to achieve adequate diuresis. If furosemide is used for more than 3 days then a potassium sparing diuretic spironolactone may be added to the treatment in a dose of 1-3 mg/kg/day (Table 2). Use of large doses can be hazardous and should be accompanied with careful monitoring of serum electrolytes. Metalazone in the dose of 0.1-0.5 mg/kg/day may also be used in refractory cases.

Table 2: Management of nephrotic edema

Furosemide (1-2 mg/kg/dose) oral or intravenous
↓
No response (no diuresis in 1-2 days)
↓
Double dose of furosemide (can go up to 10 mg/kg/day)
↓
Add spironolactone (1-3mg/kg/dose) if furosemide being used for more than 3 days
↓
No response
↓
Add metalazone (0.1-0.5 mg/kg/day)
↓
No response
↓
Change to intravenous furosemide or infusion form
↓
No response
↓
Intravenous albumin 20 percent (1 gm/kg/day)
↓
No response, try head out water immersion
↓
Ultrafiltration

Use of Albumin^{31,32}

In some cases edema is extremely pronounced with serum albumin levels below 1 gm/dl and associated hypovolemia. Diuretics are ineffective unless blood volume is expanded. 1 gm/kg salt free 20 percent albumin can be given slowly over 60 to 120 minutes with monitoring of pulse and blood pressure. Intravenous furosemide in a dose of 1 to 2 mg/kg is administered at the end of albumin infusion.

Head Out Water Immersion^{33,34}

Head out water immersion therapy, 2-4 hours each day for few days, is quite feasible in older children with parental cooperation. The procedure leads to movement of edema fluid from the interstitial to intravascular compartment. The procedure also leads to release of atrial natriuretic peptide (ANP), which inhibits sodium and water absorption from the medullary collecting duct.

Ultrafiltration

In patients with decreased GFR and heavy proteinuria ultrafiltration may be employed to remove fluid but may lead to acute renal failure if pursued too vigorously.

Hyperlipidemia^{35,36}

A host of abnormalities of lipid metabolism exist in patients with nephrotic syndrome. These include elevations in total plasma cholesterol, very low density lipoproteins, intermediate density lipoproteins, low density lipoproteins and lipoprotein A. Triglyceride levels may also be elevated. Levels of high-density lipoproteins are variable.

In steroid responsive nephrotic syndrome raised lipids fall after remission but high levels may persist in patients with heavy proteinuria or those having resistant nephrotic syndrome. Hyperlipidemia may play an important role in the development of glomerulosclerosis and progressive renal injury. The diet should contain less than 30 percent fat and low cholesterol (<200 mg/day). If dietary restrictions are not effective, then cholesterol-lowering agents may be considered. Lipid lowering drugs like atorvastatin (HMG-CoA reductase inhibitor) can be used in the dose of 0.1-0.3 mg/kg/day.

Thromboembolic complications^{37,38}

A number of abnormalities present in the nephrotic state predispose to thrombosis. These include hemoconcentration from hypovolemia, increase in blood viscosity and fibrinogen concentration, and several other abnormalities like low level of antithrombin III and protein S activity. Platelet hyperaggregability also increases the chances of thrombosis. Diuretics should be used judiciously and dehydration should be avoided. Sepsis should be treated promptly. Arterial thrombosis occurs less frequently than venous thrombosis. When the diagnosis of thrombosis is

established a loading dose of heparin 75 units/kg is given IV over 10 minutes followed by a maintenance dose of 20 units/kg/hr. Monitoring of APTT is required while patient is receiving heparin. Low molecular weight heparin (enoxaparin) can also be used in a dose of 1mg/kg/dose given twice a day. On follow up, warfarin can be given orally in dose of 0.2 mg/kg, which is continued for a period of 3-6 months. Warfarin dosage is adjusted according to INR values.

Infection^{39,40}

A number of immunological abnormalities have been documented in patients with nephrotic syndrome which predispose them to infections. These include decreased serum immunoglobulin levels due to urinary losses, impaired antibody generation, defective opsonization due to depressed level of complement factor B and abnormalities of cell mediated immunity. Infection with encapsulated organisms such as *Streptococcus*, *Haemophilus* or *Klebsiella* species is common. Aggressive antibiotic therapy should be instituted at the first suspicion of infection (Table 3).

Abnormalities of Calcium Homeostasis^{41,42}

Hypocalcemia (both total and ionized) and secondary hyperparathyroidism have been variably described in nephrotic syndrome. Potential mechanisms include reduced intestinal absorption of calcium, blunted calcemic response to parathyroid hormone, reduced levels of 25 hydroxycholecalciferol and vitamin D binding globulin (due to loss in the urine). Treatment with oral vitamin D should be prescribed in patients with evidence of hyperparathyroidism, patients with persistently low serum ionized calcium levels and in patients with unremitting or frequently relapsing nephrotic syndrome. Measurement of bone mineral density should be considered in children with persistent nephrotic syndrome

particularly if they have received large doses of steroids over long periods of time.

REDUCTION OF PROTEINURIA⁴³⁻⁴⁵

Persistent heavy proteinuria can cause progressive renal injury. In cases of steroids and immunosuppressant failure some other drugs may be used that can reduce proteinuria and retard the progression of renal disease. Indomethacin and meclofenamate can reduce proteinuria by reducing glomerular filtration and altering the capillary wall permeability, however these drugs are too toxic to be used for long time. Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB) reduce the amount of filtered protein by causing efferent arteriolar dilation and reducing glomerular filtration pressure. Enalapril in a dose of 0.2 to 0.5 mg/kg/day in 2 divided doses can cause reduction in proteinuria by 30 to 40 percent, increase in serum albumin and reduction in serum cholesterol levels. A combination of ACE inhibitor and ARB enhances the anti proteinuric effect. There are no significant side effects and long-term therapy is safe. Regular monitoring of serum creatinine and electrolytes is necessary.

Recently there has been evidence regarding use of aliskiren (anti renin drug), spironolactone (aldosterone receptor antagonist) and vitamin D and its analogs for anti proteinuric action.

CONGENITAL NEPHROTIC SYNDROME

Congenital nephrotic syndrome starts within the first three months of life or may be present at the time of birth. Finnish type (autosomal recessive) is the most common type of congenital nephrotic syndrome. Some other causes include diffuse mesangial sclerosis, primary FSGS and congenital infections like syphilis, cytomegalovirus, rubella, hepatitis B and toxoplasmosis.

The management is difficult since there is no specific treatment and mostly patients are resistant to steroids and immunosuppressive drugs. Infants with syphilis or toxoplasmosis can be initiated on specific antimicrobials. Treatment is mainly symptomatic. Edema is treated with diuretics (loop and thiazide) and albumin infusions. Dietary management in the form of high protein (3-4 gm/kg/day) and high carbohydrate diet with calcium and vitamin supplements is done. Thyroxine supplements are needed in most of the cases. ACE inhibitors and non-steroidal anti-inflammatory agents can be used to reduce GFR and proteinuria. Unilateral nephrectomy is advised in case of refractory proteinuria. Renal transplantation can be done when the child is little older or is more than 10 kgs in weight.

Renal Replacement Therapy

Nivedita Kamath, Arpana Iyengar

INTRODUCTION

The normal kidneys have several functions and play various roles in the normal physiological state in humans. Renal replacement therapy is a form of treatment that intends to replace some or all the functions of the kidney. The best form of renal replacement therapy is a renal transplant, wherein all the functions of the kidney are performed by the transplanted organ. Dialysis is an important form of renal replacement therapy both in acute kidney injury and chronic kidney disease.

Dialysis aims at performing two major functions of the kidney – solute removal—removal of urea, creatinine, middle molecules, acid and thus maintaining acid-base and electrolyte balance and fluid removal.

Renal Replacement Therapy in Acute Kidney Injury

The indications for renal replacement therapy in acute kidney injury (AKI) are:

- Symptoms of uremia
- Fluid overload
- Refractory hyperkalemia
- Refractory acidosis
- Hypercatabolic states
- Requirement of fluids/blood/blood products with oligoanuria.

Note: The degree of reduction in glomerular filtration rate or the degree of rise in creatinine value solely is not considered an indicator for RRT.

Modalities for renal replacement therapy:

- Acute peritoneal dialysis (PD)
- Intermittent hemodialysis (IHD)
- Continuous renal replacement (continuous venovenous hemofiltration [CVVH] hemodiafiltration [CVVHDF])

The choice of modality depends on the clinical condition of the patient, the availability of expertise in the

<i>Modality</i>	<i>In hemodynamic instability</i>	<i>Efficiency</i>	<i>Fluid removal</i>	<i>Anti-coagulation</i>	<i>Easy to perform</i>
Acute PD	Yes	Moderate	Moderate, uncontrolled	No	Easy
IHD	No	High	Moderate, controlled	Yes	Moderate
CVVH	Yes	Moderate	High, controlled	Yes	Moderate
CVV HDF	Yes	High	High, controlled	Yes	Difficult

hospital. The advantages and disadvantages of each of the above modalities is listed in Table 1.

ACUTE PERITONEAL DIALYSIS

Acute peritoneal dialysis is performed by insertion of a stiff polyurethane catheter or a flexible Cook's catheter percutaneously into the peritoneal cavity under local anesthesia and sedation.

The catheters are available in neonatal, pediatric and adult sizes.

Procedure for insertion of PD catheter:

- Procedure is done under sedation and local anesthesia with continuous monitoring
- Empty bladder by catheterization
- Site of insertion: infraumbilical or paraumbilical
- Create artificial ascites by instilling 10 to 20 ml/kg PD fluid into the peritoneal cavity using a 14 to 16 gauge needle
- Using a scalpel make a nick into the skin and subcutaneous tissue up to the rectus sheath
- Insert the PD catheter with stylet into the abdominal wall by a screwing motion till a loss of resistance is felt

- Withdraw stylet for 1 to 2 cm and push the catheter, directing towards left iliac fossa
- Remove stylet after ensuring that all the holes of the catheter are within the peritoneal cavity
- Connect to a 3 way connector-one end serves as inlet and other as outlet for the fluid.

Dialysis Fluid Composition

Dextrose	1.7 g/dl
Sodium	130 mEq/L
Potassium	0
Chloride	100 mEq/L
Acetate/lactate	35 meq/L
Magnesium	1.5 mEq/L
Calcium	3 mEq/L
Osmolality	355 mOsm/kg

The most commonly available PD fluid contains acetate/lactate which is converted in the liver to bicarbonate. Bicarbonate based fluid is more biocompatible and are ideal for PD. Bicarbonate based fluid is preferred in situations with liver dysfunction, lactic acidosis and inborn errors of metabolism.

Bicarbonate based fluid can be prepared using the following formula:

Solution A: 440 ml of 5 percent dextrose + 60 ml sodium bicarbonate.

Solution B: 500 ml of normal saline.

500 ml of solution B + 250 ml of solution A are mixed to obtain a fluid with sodium 140 mEq/L, bicarbonate 40 mEq/L and dextrose 1.5g/dl

Prescription

Initially four to five rapid cycles with a dwell time of 5 minutes can be done to ensure patency of the catheter.

Fill volume	20-40 ml/kg
Solution	1.7%
Fill time (inflow)	5 minutes
Dwell time	30-40 minutes (15-20 minutes in neonate)
Drain time (outflow)	10 minutes

Monitoring

Vitals	Every 30 minutes. Look for signs of respiratory compromise
Random blood sugar	Every 2 hours
Serum electrolytes, ABG	Every 4-6 hours
Serum creatinine, calcium, magnesium	Every 24 hours

Additives to PD

Heparin: 500 to 1000 U/L if PD fluid is hemorrhagic

Potassium: 4 mEq/L if serum potassium is <3.5 mEq/L

Insulin: In case of hyperglycemia.

All the above additives must be added with strict aseptic precautions to reduce the chance of infections.

Contraindications for Peritoneal Dialysis

- Abdominal wall abnormalities – omphalocele
- Diaphragmatic hernia
- Recent abdominal surgery
- Peritonitis.

Trouble Shooting

Obstruction during inflow: Consider blood clot and fibrin clot obstructing the lumen. This can be relieved by flushing the catheter and adding heparin if the fluid is blood stained.

Obstruction during outflow: Consider omentum wrapping around the catheter tip and obstructing outflow – catheter can be repositioned with all aseptic precautions.

Fluid overload: This can be handled by reducing the dwell time or increasing the concentration of dextrose in the PD fluid both of which will increase the ultrafiltration.

Hyperkalemia: Rapid cycles will facilitate removal of potassium. Reduce dwell time to 15 minutes.

Blood stained fluid: Add heparin to the fluid to prevent formation of clots.

Complications of PD

- Mechanical complications: Obstruction of the lumen by blood or fibrin clot, obstruction due to wrapping of omentum
- During insertion of catheter: Bleeding, perforation of bowel, bladder
- Infection: Cellulitis of the abdominal wall, peritonitis
- During removal of catheter: Extrusion of the omentum
- Electrolyte and metabolic abnormalities: Hyponatremia, hypokalemia, hyperglycemia, metabolic alkalosis
- Respiratory embarrassment.

INTERMITTENT HEMODIALYSIS

Intermittent hemodialysis is an effective modality of RRT in children who are hemodynamically stable.

The major advantages are:

- Short duration of therapy
- Effective for rapid treatment of fluid overload, refractory hyperkalemia and refractory acidosis.

The disadvantages are:

- Need for vascular access and anticoagulation
- Needs expertise and equipment along with trained nursing staff.

CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapy (CRRT) is a very effective modality of renal replacement therapy in acute kidney injury. Continuous veno-venous hemofiltration (CVVH) or hemodialysis (CVVHD) or hemodiafiltration (CVVHDF) are used based on the need for fluid removal alone, predominant solute removal or both respectively.

The major advantages of CRRT are:

- It is a continuous slow mode of RRT, hence suitable in patients with hemodynamic instability.
- It is a preferred mode of RRT in acute poisoning and inborn error of metabolism due to its continuous nature.
- It is the preferred mode of RRT in children with raised intracranial pressure.
- It allows for provision of parenteral nutrition

The major drawbacks are:

- Need for vascular access and anticoagulation
- The lack of expertise, infrastructure in all hospitals
- This therapy is expensive and requires trained nursing staff to conduct it.

RENAL REPLACEMENT THERAPIES IN END-STAGE RENAL DISEASE

- Chronic peritoneal dialysis:
 - Continuous ambulatory peritoneal dialysis (CAPD): This involves cycles of 4 to 8 hours dwell of dialysis fluid in the peritoneal cavity every day
 - Automated peritoneal dialysis (APD): This involves cycles at night time using a machine called the “cycler” and patient may or may not carry fluid in the cavity during the day.
- Hemodialysis and
- Renal transplantation.

Indicators to Initiate Dialysis in Chronic Kidney Disease

- *Laboratory criteria:* GFR <14 ml/min/m², refractory hyperkalemia, hyperphosphatemia and metabolic acidosis.
- *Clinical criteria:* Children with symptoms of nausea, vomiting, malnutrition, growth retardation, fluid overload, hypertension and uremia.

Strengths and limitations of chronic peritoneal and hemodialysis.

RENAL TRANSPLANTATION

Renal transplantation is the best option for children with end-stage renal disease and chronic dialysis should be considered only as a bridge to transplantation. Children are not miniature adults and have issues characteristic to transplantation in terms of the spectrum of native kidney

disease, dynamic phase of growth, pre-transplant work-up, immunization status, nutritional demands, technical expertise and psychosocial support. Children are fortunate to have donors as parents for a better graft survival and need to be on life-long immunosuppression.

Pretransplant Issues

Evaluation of lower urinary tract in children with abnormal urinary tract with deranged bladder function by a pediatric urologist is essential. Interventions to maximize bladder function like augmentation surgery may be required before transplant. Pretransplant native nephrectomy may be considered in patients with massive proteinuria, at risk for pyelonephritis, uncontrolled hypertension or those requiring more than three antihypertensive and to accommodate large donor kidneys in small children.

Operative Skills

Transplantation is usually considered when the weight of the child is above 10 kg. For children less than 15 kg, the transplant is performed through a midline incision and larger vessels like aorta and inferior vena cava are used for anastomosis with donor kidney blood vessels. The transplantation technique for children with body weight greater than 15 kg is similar to adults. Vascular thrombosis and infections are important post-transplant complications in children.

CONCLUSION

Renal replacement therapies form a crucial treatment modality for both acute kidney injury and end-stage renal disease. The responsibility of offering the best suitable and feasible option of renal replacement therapy lies in the hands of the clinician.

INTRODUCTION

Chronic kidney disease (CKD) refers to a state of irreversible kidney damage and/or reduction of kidney function which can be progressive. The term chronic kidney disease has replaced the clinical terms like chronic renal failure (CRF) and chronic renal insufficiency (CRI) which describe kidney dysfunction of varying degrees from severe to mild in nature. CKD more clearly defines kidney dysfunction as a continuum, rather than a discrete change in kidney function.

DEFINITIONS AND CLASSIFICATIONS

The definition and classification of chronic kidney disease (CKD) was introduced by the National Kidney Foundation (NKF) and Kidney Disease Outcomes Quality Initiative (K/DOQI) in 2002, and were subsequently adopted with minor modifications by the international guideline group Kidney Disease Improving Global Outcomes (KDIGO) in 2004.¹⁻³

The K/DOQI workgroup defined CKD as follows:

- The presence of markers of kidney damage for ≥ 3 months, as defined by structural or functional abnormalities of the kidney with or without a decreased glomerular filtration rate (GFR), that is manifested by either pathological abnormalities or other markers of kidney damage, including abnormalities in the blood, urine, or in imaging tests.

OR

- GFR < 60 ml/min per 1.73 m^2 for ≥ 3 months, with or without kidney damage.

The K/DOQI workgroup developed a classification system for patients greater than two years of age based upon the level of kidney function, which is independent of the primary renal diagnosis. This staging system was aimed at promoting early detection and treatment of CKD. The

stages and their definitions based upon estimated GFR are as follows:

- *Stage 1 disease:* Normal GFR (≥ 90 ml/min per 1.73 m^2)
- *Stage 2 disease:* GFR between 60 to 89 ml/min per 1.73 m^2
- *Stage 3 disease:* GFR between 30 and 59 ml/min per 1.73 m^2
- *Stage 4 disease:* GFR between 15 and 29 ml/min per 1.73 m^2
- *Stage 5 disease:* GFR of less than 15 ml/min per 1.73 m^2 or end stage renal disease (ESRD).

Normal levels of GFR vary with age, gender, and body size. GFR increases with maturation from infancy and approaches adult mean value by two years of age.^{4,5} Children under two years of age do not fit within the K/DOQI classification system because their GFR is normally lower than the GFR of older patients. Thus, the GFR of young children and infants would incorrectly place them in a stage of disease characterized by greater renal impairment than their actual renal function.

In 2004, the Kidney Disease Improving Global Outcomes (KDIGO) group modified the K/DOQI classification system for adults by adding urinary albumin excretion as an additional staging factor to the various levels of GFR. The KDIGO classification system is currently being reviewed for its relevance to pediatric CKD. Currently, the classification of CKD in children remains based on the original K/DOQI system that uses estimated GFR.

EPIDEMIOLOGY

The prevalence of CKD among children is 1.5 to 3 per 1 lakh child population. The incidence and prevalence of CKD is greater in males than females. The increased risk of CKD in males is due to the higher incidence of congenital anomalies of the kidney and urinary tract (CAKUT),

including obstructive uropathy, renal dysplasia, renal hypoplasia, and prune belly syndrome.

In the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) chronic renal insufficiency (CRI) database, which contains over 7000 patients, the age distribution at presentation was as follows:

- Below 2 years of age — 20.1 percent
- 2 years of age to below 6 years of age — 15.9 percent
- 6 years of age to below 13 years of age — 32.1 percent
- 13 years of age to below 18 years of age — 28.2 percent
- 18 to 21 years of age — 3.7 percent.

ETIOLOGY

CKD in children is the result of a heterogeneous group of disorders.

Congenital causes account for almost 60 percent of cases of CKD.⁶⁻⁸ The following distribution of causes is based upon the NAPRTCS CRI database of over 7000 patients who were registered from 1994 to 2008⁷. The distribution of causes varies with age.

- Congenital renal anomalies were present in 57 percent of cases. These anomalies included obstructive uropathy (21 percent), renal aplasia/hypoplasia/dysplasia (18 percent), reflux nephropathy (8 percent), and polycystic kidney disease (4 percent).
- Glomerular disease was present in 17 percent of patients. It was more common in older children, accounting for approximately 45 percent of cases in patients greater than 12 years of age.
- Focal segmental glomerulosclerosis (FSGS) was the most common glomerular disorder occurring in 9 percent of all CKD cases. African-American children were three times more likely to develop FSGS than Caucasian patients (18 versus 6 percent), and FSGS was the cause of CKD in one-third of African-American adolescent patients.
- Other causes accounted for approximately 25 percent of cases. In 18 percent of all cases of CKD, the underlying primary diagnosis was not identified (15 percent) or was unknown (3 percent). Other more uncommon causes of CKD in children included hemolytic-uremic syndrome, genetic disorders (e.g. cystinosis, oxalosis, and hereditary nephritis (also referred to as Alport's syndrome)), and interstitial nephritis. Unlike adults, diabetic nephropathy and hypertension were rare causes of CKD in children.

NATURAL HISTORY AND PROGRESSION OF CHRONIC KIDNEY DISEASE

The natural history of renal disease is variable and, at times, unpredictable. The initial injury to the kidney may result in a variety of clinical manifestations. In some cases, individuals may fully recover and suffer little or no sequel,

like patients with post streptococcal glomerulonephritis or in most children with hemolytic-uremic syndrome.

In children with CKD, the persistent deterioration of renal function may be a result of repeated and chronic insults to the renal parenchyma leading to permanent damage and/ or to the adaptive hyperfiltration response of the kidney, which compensates for the loss of nephrons from the initial injury.⁹

Over time, however, the enhanced transglomerular ultrafiltration and glomerular pressure leads to glomerular damage and leakage of protein resulting in interstitial inflammation and fibrosis. This long-term injury is characterized histologically by glomerulosclerosis, vascular sclerosis, and tubulointerstitial fibrosis,¹⁰⁻¹² and clinically by proteinuria and progressive renal insufficiency (Fig. 1).

The rate of progression of CKD is usually greatest during the two periods of rapid growth, infancy and puberty, when the sudden increase in body mass results in a rise in the filtration demands of the remaining nephrons. As a result, children with CKD should be closely monitored during these two periods for an accelerated progression of CKD. In addition to the increase in body mass, hormonal changes during puberty may also contribute to the rapid decline in renal function seen in adolescence.

The rate of progression to ESRD in childhood is inversely proportional to the baseline creatinine clearance (CrCl) at presentation. In addition, genetic, familial or ethnic predisposition may influence the rate of renal decline. Other factors associated with an increase in the rate of CKD progression include primary disease, hypertension, proteinuria, anemia, hyperphosphatemia and hypocalcemia.¹³

Despite the high mortality rates of very young children with ESRD, good long-term outcomes can be achieved.

CLINICAL PRESENTATION

The clinical presentation of CKD is dependent upon the severity of renal impairment and the underlying disorder.

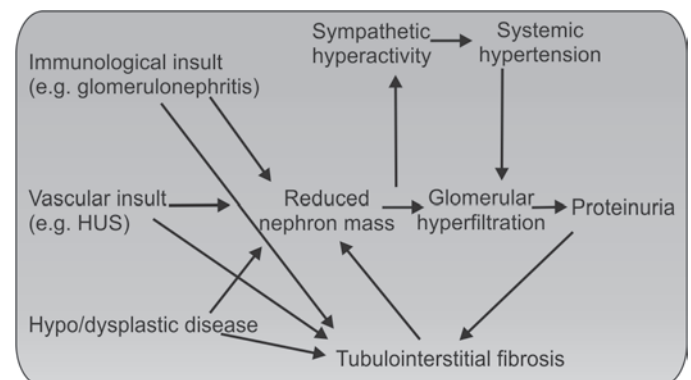

Fig. 1: Mechanism of progression of chronic kidney disease

Patients presenting during the early stages of CKD (e.g. stages 1 and 2) are typically asymptomatic. As CKD progresses and renal function deteriorates, patients become increasingly symptomatic.

In view of the heterogeneity of causes for pediatric chronic kidney injury, signs and symptoms vary and include different amounts of urine output (polyuria, oliguria, or anuria), edema, hypertension, and/or discolored urine. Patients with glomerular disease may present with hematuria, proteinuria, hypertension, and edema in the early stages of CKD, which may persist into later stages.

Patients with renal disease may present in a variety of ways:

- Polyuria may be an early presenting finding because many congenital anomalies of the kidney and urinary tract (e.g. obstructive uropathy), inherited disorders (e.g. nephronophthisis), and tubulointerstitial disorders are associated with reduced concentrating ability (i.e. nephrogenic diabetes insipidus). In these conditions, the impairment in renal concentration generally precedes a significant reduction in GFR.
- Elevation in the serum creatinine concentration and/or abnormalities on urinalysis.
- Proteinuria is a strongly-associated biomarker of CKD and is a possible sign of underlying glomerular disease or tubular dysfunction. Persistent (≥ 3 months) increased excretion of urinary protein in a nonorthostatic pattern is indicative of CKD.¹⁴
- Detection of congenital or structural anomalies by imaging studies, particularly prenatal ultrasonography.
- Poor growth is a common manifestation of CKD in children.
- Symptoms and/or signs of severe renal impairment or renal failure begin to appear in some patients with stage 3 disease and are present in those with stages 4 and 5 disease. These symptoms (referred to as symptoms of uremia) include anorexia, and vomiting, weakness and easy fatigability. Other findings attributable to the uremic state include pericarditis, deficits in neurocognitive function and osteodystrophy.
- Systemic symptoms and findings like fever, arthralgias/ arthritis, rash or pulmonary symptoms, depending upon the concurrent systemic disease that affects renal function resulting in CKD, such as lupus nephritis or Wegener's granulomatosis.

COMPLICATIONS OF CHRONIC KIDNEY DISEASE

A moderate to severe loss of GFR (i.e. stage 3 to 5 disease), is associated with a number of complications due to impairment of the many functions performed by the kidney. These complications may be the presenting sign or symptom of CKD and include:

- Disorders of fluid and electrolytes—hyponatremia or hypernatremia, hypokalemia or hyperkalemia, metabolic acidosis, fluid overload
- Disorders of mineral metabolism and renal osteodystrophy
- Anemia
- Hypertension
- Dyslipidemia
- Endocrine abnormalities—abnormalities of thyroid hormone, growth hormone and gonadal hormones metabolism
- Growth impairment
- Decreased clearance of renally excreted substances from the body (uremia).

EVALUATION AT PRESENTATION

The evaluation of a child with CKD begins with a history and physical examination. Imaging and laboratory evaluation are useful to determine the underlying cause of CKD, severity of renal impairment and whether any associated complications of CKD are present.

Clinical Evaluation

History

The history should include documentation of the age at onset of symptoms, duration of symptoms, type of symptoms due to uremia (weakness, fatigue, anorexia, or vomiting), systemic diseases (fever, rash, or arthralgias/ arthritis), or specific renal disorders (e.g. glomerulonephritis with hematuria and/or edema).

The history is focused on signs of CKD or factors that increase the risk of CKD, the list of which should include the following:

- Family history of renal disease or hypertension
- Growth history, particularly poor linear growth
- Polyuria, polydipsia or enuresis
- Elevated blood pressure
- Antenatally diagnosed congenital anomaly of the kidney or urinary tract (CAKUT)
- Orthopedic or urologic abnormalities
- Recurrent urinary tract infection
- Unexplained anemia
- Seizures
- Fluid and electrolyte disorders.

Physical Examination

The physical examination of any child suspected of having CKD should include:

- Measurement of growth parameters (height, weight, and for patients ≤ 5 years of age, head circumference), as these children are at risk for poor growth.
- Blood pressure measurement, as hypertension often occurs in children with CKD due to underlying renal

pathology, hypervolemia due to impaired water excretion or certain medications.

- Pallor as an indication of anemia should be assessed.
- Examination of the extremities for any deformity as an indication of chronic kidney disease—metabolic bone disease (CKD-MBD) or edema as an indication of nephrotic syndrome. The site and type of deformity of the extremities depend upon the age of the child and the weight-bearing patterns in the limbs, and are similar to those found in children with rickets. Thus, deformities of the forearms and posterior bowing of the distal tibia are found more commonly in the infant, whereas an exaggeration of the normal physiological bowing of the legs (genu varum) is a characteristic finding in the toddler who has started to walk. In the older child, valgus deformities of the legs or a windswept deformity (valgus deformity of one leg and varus deformity of the other) may be apparent.
- Assessment for any sign of hypervolemia by noting the presence/absence of edema, rales, hepatic enlargement/tenderness, or cardiac gallop.
- Cardiac auscultation to detect a pericardial rub due to pericarditis or diminished heart sounds secondary to a pericardial effusion.

Imaging

Imaging may be useful in identifying the underlying cause of CKD and assessing a decrease in renal parenchyma.

Ultrasonography (US) is the most widely used modality and is a noninvasive procedure. It assesses the growth and the structure of the kidneys. The ultrasound examination should compare the measured length of each kidney to normative age-appropriate values.¹⁵⁻¹⁷ Kidneys that are smaller than normal indicate a decrease in renal mass due to congenital maldevelopment (e.g. renal hypoplasia), poor growth, or loss of nephrons due to an underlying disorder or injury.

Other imaging studies include voiding cystourethrogram (VCUG), computed tomography (CT), and magnetic resonance imaging (MRI), which are used in specific clinical settings, or when better resolution or visualization is required than that provided by ultrasonography.

Laboratory Testing

Depending on the type of kidney disease, blood and urine studies are often used to support the diagnosis of CKD.

- *Serum creatinine:* To know the degree of renal damage and for calculation of GFR.
- *Electrolytes:* To detect electrolyte abnormalities, particularly hyperkalemia and metabolic acidosis.
- *Complete blood count:* To detect anemia.
- *Red blood cell indices:* If the red blood cell indices are not consistent with a normocytic and normochromic anemia, which usually characterizes the anemia of CKD, then another cause of anemia should be considered.

- Reticulocyte count.
- Tests to determine iron status (serum iron, total iron binding capacity, percent transferrin saturation)
- Test for occult blood.
- Serum calcium, phosphorus, 25-hydroxyvitamin D, and parathyroid hormone level to detect any abnormalities in bone mineral metabolism.
- Fasting lipid profile that includes total cholesterol, low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C) and triglycerides (TG) to detect the presence of dyslipidemia.
- *Urinalysis:* Urinalysis is a useful screening test for abnormalities of the kidney and urinary tract, and as an aid in identifying the underlying cause of CKD. The urinary dipstick makes it possible to test for protein, pH, concentration, glucose, hematuria, and pyuria. Different patterns of urinary findings are associated with both acute and chronic kidney disease.
- Proteinuria is an indicator of underlying glomerular disease and/or tubular dysfunction, and is an important biomarker strongly associated with CKD. Ongoing urinary protein excretion may contribute to the progression of CKD. The severity of renal disease is generally associated with the amount and duration of proteinuria. Therefore, persistent high-grade proteinuria (2+ protein or greater) usually warrants a prompt evaluation for other signs of renal dysfunction. Lower levels of protein detected by urinary dipstick can usually be followed with repeated measurements to determine if there is resolution of proteinuria. The presence of persistent proteinuria by dipstick evaluation should be quantified by determination of the urine protein/creatinine ratio.
- *Kidney biopsy:* Tissue samples obtained via kidney biopsy are typically evaluated by light microscopy, immunofluorescence staining and electron microscopy. Data from these studies may be useful in providing a diagnosis for the cause of CKD and guiding therapeutic choices.

MANAGEMENT

General Principles

The general management of the patient with CKD includes the following components:

- Treat reversible kidney dysfunction
- Prevent or slow the progression of kidney disease
- Treat the complications of CKD
- Identify and adequately prepare the child/family in whom renal replacement therapy will be required.

The timing of implementing these components varies primarily upon the severity of CKD.

In the early stages of CKD, there is an opportunity to treat any reversible cause of kidney dysfunction, and prevent or slow the progression of kidney disease. Children with stages 1 and 2 disease are asymptomatic and should be

closely followed for deterioration of kidney function. This period should also be used to educate the child and family about CKD, highlighting awareness of risk factors that can aggravate kidney failure (e.g. nephrotoxic drugs, recurrent infections, dehydration) and of measures that may slow the progression of kidney failure (e.g., blood pressure control).

CKD-associated complications begin to appear as CKD progresses into stage 3. These include disorders of fluid and electrolytes, renal osteodystrophy, anemia, hypertension, dyslipidemia, endocrine abnormalities, growth impairment, and disorders due to the decreased clearance of substances normally excreted from the body by the kidney (uremia). In these patients, management is focused on preventing and treating these complications.

Patients who will require renal replacement therapy (RRT) should be identified well in advance of the time that RRT is required so that adequate preparation and education can be provided to both the patient and family. This generally occurs in patients with stage 4 CKD.

Reversible Kidney Dysfunction

In children with CKD, identification and treatment of reversible causes of acute or chronic kidney dysfunction may result in some recovery of kidney function, if addressed early in the course.

The most common conditions with potentially recoverable kidney function are primarily due to decreased kidney perfusion or the administration of nephrotoxic agents.

- *Decreased kidney perfusion:* Kidney hypoperfusion is produced by hypotension (e.g. septic shock), volume depletion from vomiting, diarrhoea, diuretic use, or bleeding, and the administration of drugs that lower the kidney perfusion (such as nonsteroidal anti-inflammatory drugs, angiotensin converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs)).
- If significant hypovolemia accompanied by a reduction of GFR occurs, a judicious trial of fluid repletion may result in the return of kidney function to the previous baseline.
- *Administration of nephrotoxic drugs:* Common nephrotoxic drugs include nonsteroidal anti-inflammatory agents, diagnostic agents (e.g. radiographic contrast materials), and others (e.g. aminoglycosides, amphotericin B, cyclosporine, and tacrolimus). The administration of such drugs, therefore, should be avoided or used with caution in patients with underlying CKD, with the assistance of therapeutic drug level monitoring.

Slowing CKD Progression

In patients with CKD, progressive long-term kidney damage is in part due to adaptive hyperfiltration with increased intraglomerular perfusion and pressure. The kidney injury is manifested histologically by glomerular scarring (glomerulosclerosis). The progression of CKD is

greatest during the two periods of rapid growth: infancy and puberty. These events place increased demands upon the preexistent compromised kidney function.

Blood Pressure Control

In CKD, strict blood pressure control has been shown to slow the progression of kidney disease and reduce the risk of cardiovascular disease. In particular, ACE inhibitors and ARBs have been suggested as antihypertensive therapy to reduce proteinuria and control blood pressure in these patients.

Other Interventions

Additional interventions include lipid lowering therapy and correction of anemia. In relation to protein intake, the current consensus by pediatric nephrology experts is to provide children with CKD the age appropriate recommended daily allowance for protein.

CKD COMPLICATIONS

A wide range of complications result as a consequence of the loss of kidney function. These include disorders of fluid and electrolyte balance, renal osteodystrophy, hypertension, anemia, dyslipidemia, growth impairment, malnutrition and risk of poor neurodevelopmental outcome.

Sodium and Intravascular Volume

As GFR becomes severely decreased (i.e. stages 4 and 5 disease), water and sodium retention may result in volume overload. In general, a combination of dietary sodium restriction and diuretic therapy may correct the increased water balance and prevent water retention from recurring.

Diuretic therapy includes either loop diuretics such as furosemide given at a dose of 0.5 to 2 mg/kg per day or thiazide diuretics such as hydrochlorothiazide at 1 to 3 mg/kg per day. Thiazide diuretics are usually used in the early stages of CKD and a loop diuretic in the more advanced stages of disease when the thiazides are less effective. Both classes of diuretics become less effective with decreasing GFR.

Some children with obstructive uropathy and/or dysplastic kidneys have poor urinary concentrating capacity and exhibit urinary sodium wasting, resulting in a propensity for hypovolemia and hyponatremia. In these children the need for fluid replacement should be emphasized to the caretakers, especially when the child has an intercurrent illness that increases volume losses (e.g. diarrhea) or decreases fluid intake (e.g. vomiting).

Hyperkalemia

Hyperkalemia develops primarily because of inadequate potassium excretion due to a reduced GFR. Other factors that can contribute to elevated potassium levels include a high dietary potassium intake, increased tissue breakdown,

metabolic acidosis, hypoaldosteronism (due in some cases to administration of an ACE inhibitor or an ARB), or an impaired cellular uptake of potassium.

Management to prevent hyperkalemia in children with CKD consists of the following:

- Low potassium diet.
- Administration of a loop diuretic (e.g. furosemide) to increase urinary potassium loss.
- If there is metabolic acidosis, oral sodium bicarbonate to correct acidosis.
- In infants under selected circumstances, formula can be mixed with sodium polystyrene sulfonate and decanted externally to decrease the potassium content of the formula prior to feeding.¹⁸ The use of sodium polystyrene sulfonate in this manner is a common practice in many pediatric nephrology centers.

Renal replacement therapy must be considered if conservative management fails to control hyperkalemia.

Hypokalemia is uncommon in children with CKD. However, it can be observed in children in the early stages of CKD associated with Fanconi syndrome, renal tubular acidosis, or from excessive diuretic therapy.

Metabolic Acidosis

In children, overt acidosis is characteristically present when the estimated GFR is less than 30 ml/min per 1.73 m² (i.e. stage 4 disease). Acidosis is associated with growth impairment because the body utilizes bone buffering to bind some of the excess hydrogen ions.

Current guidelines by the K/DOQI working group are to maintain the serum bicarbonate level at or above 22 mEq/L.¹⁹ Sodium bicarbonate therapy is suggested in patients with metabolic acidosis to achieve this targeted goal.¹⁹ Sodium bicarbonate therapy is started at 1 to 2 mEq/kg per day in two to three divided doses, and the dose is titrated to the clinical target.

Bone Metabolism and Bone Disease

Changes in mineral metabolism and bone structure are an almost universal finding with progressive CKD due to abnormalities in the metabolism of calcium, phosphate, vitamin D, and parathyroid hormone (PTH) levels.^{19,20} If these abnormalities are not addressed, these changes result in kidney bone disease, referred to as renal osteodystrophy. Significant morbidity may be associated with renal osteodystrophy, including growth failure, avascular necrosis, skeletal fractures and deformities.

Hypertension

Strict blood pressure control is recommended in all children with CKD. Treatment of hypertension should include specification of target blood pressure levels, nonpharmacologic therapy and antihypertensive therapy.

Target Blood Pressure Goals

In children with CKD, the National High Blood Pressure Education Program Working Group (NHBPEP) has recommended a reduction in blood pressure to below the 90th percentile based upon the age, gender, and height of the patient.²¹ The K/DOQI guidelines also recommend a target systolic and diastolic blood pressures of less than 90th percentile for age, gender, and height, or less than 120/80 mm Hg, whichever is lower.

Therapeutic Interventions

Therapy includes both nonpharmacologic and pharmacologic interventions:

- *Nonpharmacologic therapy:* Treatment should be initiated with conservative measures such as weight reduction, exercise and dietary salt reduction. The current recommendation for adequate daily sodium intake is only 1.2 g/day for four to eight year olds and 1.5 g/day for older children.²¹
- *Pharmacologic therapy:* The ACE inhibitors or angiotensin II receptor blockers (ARBs) may be used for treatment of hypertension in the earlier stages of CKD. They are the preferred antihypertensive agents as they appear to be more beneficial in slowing the progression of CKD compared to other agents in patients with CKD.²²⁻²⁵ Enalapril is often started at an initial dose of 0.08 mg/kg per day (maximum of 5 mg/day), and is titrated to a maximum dose of 0.6 mg/kg per day (maximum of 40 mg/day) based upon the response of the patient's blood pressure and results of lab tests (e.g. serum potassium). Enalapril is used because its long half-life and it allows once a day dosing. Alternatively we can use other long-acting ACE inhibitors like lisinopril and ramipril.

Both ACE inhibitors and ARBs should be used cautiously if the GFR is less than 60 ml/min per 1.73 m².²⁵ Since the decline in GFR induced by an ACE inhibitor typically occurs within the first few days after the onset of therapy, the serum creatinine and potassium concentrations should be remeasured three to five days after the institution of therapy to ensure that the therapy has not adversely affected the GFR resulting in elevation of serum creatinine and/or hyperkalemia.

A diuretic is also often recommended in the early stages of CKD. The thiazide diuretics, such as hydrochlorothiazide (1–3 mg/kg per day to a maximum of 50 mg/day), become less effective as monotherapy as the GFR declines. Thus, a loop diuretic is recommended for the treatment of hypertension and edema in patients with more severe CKD. Preferred loop diuretic is furosemide at a dose of 0.5 to 2 mg/kg per day in one to two divided doses.

Anemia

Anemia due to reduced kidney erythropoietin production generally develops when the GFR is below 30 ml/min per 1.73 m². The presence of anemia in children with CKD is very common and has been associated with excessive morbidity and an increased mortality risk.²⁶

Because anemia is a common complication of children with severe CKD (i.e. stages 4 and 5), the K/DOQI work group established guidelines for the identification, evaluation, and treatment of anemia in children at all stages of CKD.²⁷ The recommendations for the management of anemia presented here are based upon these guidelines.

Screening and Evaluation of Anemia

Annual testing of hemoglobin (Hgb) should be performed in children with CKD, regardless of stage or cause.

A diagnosis of anemia is made when the observed hemoglobin result is below the fifth percentile of normal adjusted for age and sex. Once anemia is detected in a child with CKD, the following evaluation, which is focused upon eliminating causes of anemia other than CKD and determining the iron status of the patient, is recommended:

- Red blood cell indices
- Reticulocyte count
- Iron parameters (serum iron, total iron binding capacity, percent transferrin saturation (TSAT) and serum ferritin)
- Test for occult blood in stool.

Treatment of Anemia

The treatment of anemia in children with CKD often includes iron supplementation and erythropoiesis stimulating agent (ESA).

Iron therapy (elemental iron 3–4 mg/kg per day) should be initiated if iron deficiency is detected. Iron supplementation is targeted to maintain a TSAT \geq 20 percent and serum ferritin \geq 100 ng/dL in children with CKD. All patients receiving therapy with an ESA, such as recombinant human erythropoietin (rHuEPO) and darbepoetin alfa, require iron supplementation to prevent the development of iron deficiency. Once iron status is normal, it should be monitored at least every three months, or monthly following the initiation of and/or increase in ESA dosing.

Increasing the hemoglobin (Hgb) into an acceptable range in patients with anemia may ameliorate anemia-induced symptoms (e.g. fatigue and exercise intolerance), result in cardiovascular improvement and possibly decreased mortality. K/DOQI guidelines, recommend a target hemoglobin between 11 and 12 g/dL based upon consensus expert opinion.^{27,28}

The initial rHuEPO dose in older children not receiving dialysis is 80 to 120 u/kg per week, administered in two

to three divided doses. Children younger than five years of age or children receiving dialysis frequently require higher doses (300 u/kg per week). In predialysis patients and in those who receive peritoneal dialysis, rHuEPO should preferably be administered by the subcutaneous route and the site of injection should be rotated. In patients who receive hemodialysis, erythropoietin is typically administered intravenously through their vascular access.

Darbepoetin alfa is a long-acting erythropoietic agent. Its threefold longer half-life and greater biological activity compared to recombinant erythropoietin allows for less frequent dosing to effectively maintain a target Hgb. Based upon limited pediatric data, darbepoetin alfa can be given at a dose of 0.25 to 0.75 mcg/kg once weekly.^{29,30}

Dyslipidemia

Abnormal lipid metabolism is common in patients with CKD and adds to the risk for cardiovascular disease (CVD) in children with CKD. K/DOQI, the American Heart Association (AHA) and the American Academy of Pediatrics (AAP) recommend that all adolescents with CKD should be evaluated for dyslipidemia.^{19,31,32} Evaluation is performed by obtaining a fasting lipid profile that includes total cholesterol, low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C) and triglycerides (TG) at presentation, and annually thereafter or two to three months following a change in treatment or subsequent to the presentation of another condition known to cause dyslipidemia.

The following treatment guidelines have been suggested by the AHA and the AAP for children with CKD and dyslipidemia based upon a literature review by an expert panel:³²

- **Fasting TG >150 mg/dL:** Interventions initially include therapeutic lifestyle changes, such as a decreased intake of simple sugars; in patients with TG >700 mg/dL consider administration of a fibric acid, such as gemfibrozil or fenofibrate.
- **HDL <35 mg/dL:** Therapeutic lifestyle changes, such as vigorous daily physical activity of greater than 60 minutes, weight loss, and dietary substitution of monounsaturated for saturated fatty acids.
- **LDL \geq 100 mg/dL:** Therapeutic lifestyle changes including a low-saturated-fat, low-cholesterol diet and a daily exercise regimen. In children greater than 8 years of age, the use of statin therapy can be considered.

Nutrition

Malnutrition is common in children with CKD because of poor appetite, decreased intestinal absorption of nutrients, and metabolic acidosis. Attention to nutrition is critical as it affects both the physical growth and neurocognitive development of children.

Energy

The initial prescribed energy (calorie) for children with CKD is based upon the estimated energy requirement (EER) for chronological age.¹⁹ Further supplementation should be considered when the initial intake fails to meet the child's energy requirements and he/she is not achieving expected rates of weight gain and/or growth. Although supplementation by the oral route is preferred, one may have to resort to tube feedings with a nasogastric tube, transpyloric tube, or gastrostomy to ensure adequate energy intake. A trial of intradialytic parental nutrition may be considered in children undergoing chronic hemodialysis therapy.

Protein

Protein intake should be between 100 and 140 percent of the Dietary Reference Intake (DRI) based upon age and gender for children with CKD stage 3 and between 100 and 120 percent for those with CKD stages 4 and 5.¹⁹ Protein restriction is not recommended in children as it has not been shown to influence the decrease in kidney function in children with CKD. Supplementation should be considered if the oral and/or enteral protein intake is inadequate.^{19,33,34}

Vitamins and Minerals

Children with CKD should receive 100 percent of the DRIs for the vitamins, thiamine (B1), riboflavin (B2), pyridoxine (B6), vitamin B12, A, C, E, K, and folic acid, and the minerals, copper and zinc.¹⁹ In children with advanced CKD (i.e. stage 5), the loss of renal clearance of vitamin A metabolites places these children at risk for developing hypervitaminosis and these children should receive a water-soluble vitamin supplement.

Growth

Growth failure has been long recognized in children with CKD. While the institution of recombinant human growth hormone (rHuGH) therapy can have a profound effect on the height velocity of children with CKD who are growing poorly, early recognition and management of malnutrition, renal osteodystrophy, acid-base abnormalities and electrolyte disturbances should take place prior to considering the institution of rHuGH.

The use of rHuGH is continued until the child reaches the 50th percentile for mid-parental height, achieves a final adult height with closed epiphyses or receives a kidney transplant. The initial dose of rHuGH in children with CKD is currently 0.05 mg/kg per day (which corresponds to 4 IU/day per m² body surface area or 1 IU/kg per week); rHuGH is given daily via subcutaneous injections.

Neurodevelopment

Uremia is associated with alterations in cognition and may impact neurodevelopment in children. Neurologic findings can range from seizures and severe intellectual disability (mental retardation) to subtle deficits resulting in poor school performance.³⁵

Neurodevelopmental impairment can be minimized by optimizing nutritional, dialysis, and anemia management. In infants and young children, frequent monitoring of head circumference and age-appropriate developmental evaluations are necessary. The cognitive disturbance in an older child may present with abnormal performance on tasks of verbal abstract ability, visual perceptual reasoning, memory, and visual motor skills. A more formal neurodevelopmental assessment is needed in older children, especially if they have poor school performance. Educational support can be obtained by referral to early intervention programs for infants and young children or special education school services.

Uremic Bleeding

An increased tendency for bleeding is present in patients with severe CKD due primarily to abnormalities in platelet adhesion and aggregation properties. In asymptomatic patients, no specific therapy is required.

However, in patients who are actively bleeding or who are about to undergo a surgical or invasive procedure (such as renal biopsy), the platelet abnormality should be addressed. A number of different treatment options can be considered in this setting. These include the following:

- Desmopressin (dDAVP), an analog of antidiuretic hormone that is the simplest and least toxic acute treatment. It is administered intravenously or subcutaneously at a dose of 0.3 mcg/kg with an onset of effect within one hour of administration; the effect lasts for six to eight hours.
- Cryoprecipitate (1–2 units/10 kg); the effect lasts for 24 to 36 hours.
- Estrogen (0.6 mg/kg per day for 5 days); the onset of effect is over 6 to 24 hours, but the effect lasts for two to three weeks.
- Correction of anemia; an improved hemoglobin (hematocrit) is believed to facilitate increased interaction between platelets and blood vessels.

Uremic Pericarditis

Uremic pericardial disease (pericarditis and pericardial effusion) is seen only in the late stages of CKD and is an indication to institute dialysis. Most patients with uremic pericarditis respond rapidly to dialysis with resolution of chest pain as well as a decrease in the size of the pericardial effusion.

Renal Replacement Therapy

Once the estimated GFR declines to less than 30 mL/min per 1.73 m² (stage 4 CKD), it is time to start preparing the child and the family for renal replacement therapy.¹ The family should be provided with information related to pre-emptive kidney transplantation, peritoneal dialysis and hemodialysis.

As in adults, some form of renal replacement therapy will generally be needed when the GFR falls below 15 mL/min per 1.73 m² (stage 5 CKD). However, renal replacement therapy is often initiated before children reach these levels for the following reasons:

- Poor total calorie intake resulting in failure to thrive
- Clinical symptoms attributable to uremia
- Delay in psychomotor development and/or educational issues from progressive CKD.

Choice of Renal Replacement Therapy

The choice of replacement therapy in children is variable. The registry of the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) reports that of patients initiating renal replacement therapy in pediatric centres:^{7, 36}

- One quarter of children underwent pre-emptive renal transplantation
- One half were started on peritoneal dialysis
- One quarter were started on hemodialysis.

The high incidence of pre-emptive renal transplantation in children is due to having parents who are a half haplotype match, who are relatively young and healthy, and are willing to donate a kidney. In addition, pediatric nephrologists frequently follow their patients from the early stages of CKD and can prepare the patient and their family for transplantation and avoid initiating dialysis.

When pre-emptive transplantation is not an option, the choice between the two forms of dialysis is generally dictated by technical, social, compliance issues and family preference. Peritoneal dialysis is much more common in infants and younger children,³⁷ in large part due to problems of vascular access; hemodialysis becomes more common in older adolescents. However, hemodialysis can be performed successfully in infants and very young children, as well.³⁸

Children who elect to receive hemodialysis will need evaluation of their vasculature for placement of an arteriovenous (AV) fistula, arteriovenous graft or cuffed double lumen catheter. The use of an AV fistula, the recommended type of vascular access in adults, is limited in children due to the size of their vessels. In the 2008 NAPRTCS annual report, vascular access for hemodialysis included external percutaneous catheter in 77.7 percent of patients, internal AV fistula in 12.3 percent, and internal and external AV shunt in 7.3 and 0.7 percent, respectively.⁷ K/DOQI has recently encouraged greater use of AV fistulas in larger children receiving hemodialysis who

are not likely to receive a transplant within 12 months, with a goal of achieving more effective dialysis with fewer complications (e.g. infection) than occurs with catheters.

Children who are to initiate peritoneal dialysis undergo abdominal surgery for placement of a peritoneal dialysis catheter. Peritoneal dialysis is more common in infants and young children than hemodialysis due to the above mentioned vascular access problem. Peritoneal dialysis can be performed by parents at home, overnight with a cycling machine. The use of a cycler potentially allows the least disruption of home life, school, and work attendance, when compared to ambulatory peritoneal dialysis, which often requires a peritoneal dialysis exchange procedure to be conducted during the daytime, or hemodialysis, which usually requires three weekly treatments of at least three to four hours (not counting travel time). In addition, access to a nearby hemodialysis centre may not be readily available to patients and their families or the centre personnel may not be trained to care for children, especially prepubertal children and infants.

Quality of Life

CKD, as is true for any chronic condition, impacts on the quality of life for both the child and family. A survey of 402 families of 2 to 16 year old children with mild to moderate CKD (median GFR 42.5 mL/min per 1.73 m²) of median duration of seven years found an overall low health related quality of life in children with CKD.³⁹ They scored lower compared to their healthy peers in all of the four domains tested: physical, school, emotional, and social.

In particular, psychological and social stresses are found in children with CKD and their families. The normal progression of the child to independence is impeded, and concerns about body composition and image are greatly magnified in children whose growth and pubertal development are delayed or altered. The prospect of a lifetime with renal replacement therapy (dialysis and/or transplant) and the potential for catastrophic complications and/or death makes it difficult to achieve normal childhood and adolescent developmental goals.^{40,41}

This difficulty continues into adulthood as demonstrated in a study of 144 adults who had childhood ESRD.⁴² Compared to age-matched population normative data, these patients were twice as likely to be unemployed (19 versus 11%), and those who were employed were at a lower occupational level.

The negative impact of chronic disease on the emotional status of the patient's siblings is also well recognized.⁴³ These siblings frequently feel "neglected" because the parents must provide substantial physical and psychological support to the sick child. Furthermore, the well child may simultaneously feel jealous of the attention provided to the sick child, as well as guilt about being well while the sibling is severely ill.

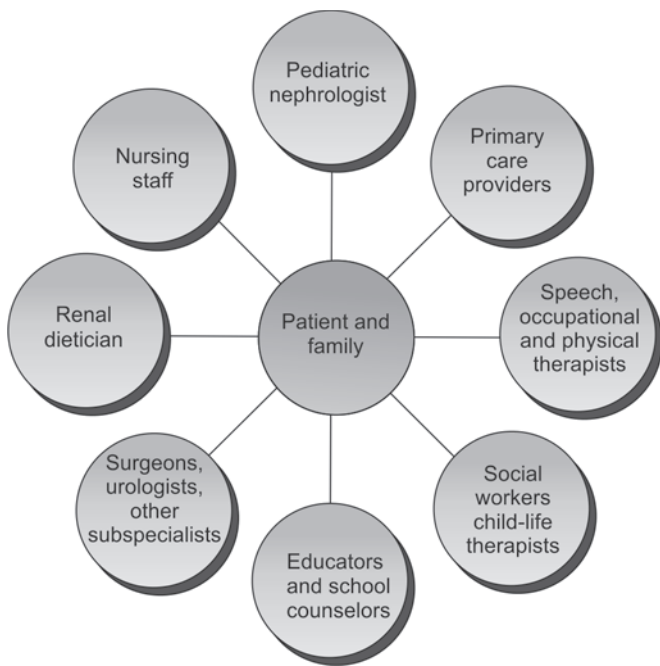

Fig. 2: Multidisciplinary care model for children with chronic kidney disease

Optimal comprehensive management of these issues involves a multidisciplinary approach that proactively addresses these concerns (Fig. 2). Key members of the team include social workers and mental health specialists.

When, on a rare occasion, parents of a child with stage 5 CKD elect conservative management and death over a lifetime of dialysis and transplantation for their child, this should be considered a choice that may, on occasion, be medically, ethically and legally acceptable. A host of factors need to be considered by the family, the healthcare providers, and often the institution's ethics committee. When a decision to forego renal replacement therapy is deemed acceptable, the family should be supported emotionally and provided with whatever care is necessary to maintain the child in a pain-free state.⁴⁴

Voiding Disorders in Children

Madhuri Kanitkar, H Ravi Ramamurthy

INTRODUCTION

The urinary bladder is an organ interspersed between the kidneys and the external environment to ensure continence, i.e. to void at an appropriate place and time. The genitourinary system controlled by complex neural pathways ensures this function. An aberration of this mechanism, once bladder control has been achieved results in a voiding disorder. These children may present with nocturnal enuresis, altered voiding frequency, day time incontinence, urgency, hesitancy, straining, weak stream, holding maneuvers, a feeling of incomplete emptying, postmicturition dribble and genital or lower urinary tract (LUT) pain. These features may be seen in isolation or in varied combinations in a child. Such children suffer physical discomfort, psychological distress and may result in irreversible damage to the urinary system including renal failure. Recent studies have shown that untreated voiding disorders in childhood affects multiple systems, notably bowel, bladder, sexual and ejaculatory function, blood pressure, and even mood and behavior even in adult life.¹ Therefore, the usual approach of “*the child will grow out of it*” or “*they would not be wetting themselves on their wedding day*” needs to be replaced by a caring, scientific approach on part of the pediatrician with the involvement of parents and the child in treatment of this disorder.

NORMAL VOIDING AND ITS CONTROL

The main functions of the urinary bladder are storage and expulsion. At birth, micturition occurs spontaneously as a spinal cord reflex. Between one and two years of age there is a gradual increase in the bladder capacity along with neural maturation of the frontal and parietal lobe. The fully mature system has a normal bladder capacity, voluntary control of the external sphincter and an ability of the cerebral cortex to initiate and inhibit a detrusor contraction for any bladder capacity² (Fig. 1).

Fig. 1: The neurological control of Micturition: Coordinated contraction of detrusor muscles along with relaxation of the bladder sphincter is necessary for micturition. The sympathetic system is responsible for bladder filling and the parasympathetic system for micturition. The somatic and the central nervous system ensure cortical control of voiding, thus preventing enuresis

ETIOLOGICAL CLASSIFICATION OF VOIDING DISORDERS IN CHILDREN

- Enuresis
 - *Monosymptomatic enuresis*: Enuresis in children without any other LUT symptoms and without a history of bladder dysfunction.
 - *Non-monosymptomatic enuresis*: Enuresis along with any other LUT symptoms like nocturnal enuresis, altered voiding frequency, day time incontinence, urgency, hesitancy, straining, weak stream, intermittency, holding maneuvers, a feeling of incomplete emptying, postmicturition dribble and genital or LUT pain. This condition is broadly grouped as functional voiding disorders (FVD) and are sub classified as:
 - a. Overactive bladder (OAB) or urge incontinence: It manifests as urinary urgency and day time wetting.
 - b. Voiding postponement: Children habitually postpone micturition, often using holding maneuvers.
 - c. Dysfunctional voiding (DV): The child habitually contracts the urethral sphincter during voiding thus producing bladder sphincter dysynergia.
 - d. Underactive bladder: Children with low voiding frequency, large capacity bladder and need to strain while voiding.³
- Neurogenic bladder
- Congenital anomalies/Anatomical defects
- Others (Rare): Stress incontinence, vaginal reflux, giggle incontinence and extraordinary day time urinary frequency.

EPIDEMIOLOGY

Eighty-five percent children are dry by five years of age.⁴ But recent studies have shown that in children of around 7 years of age, the prevalence of nocturnal enuresis is 15.5 percent.⁵ Up to the age of nine years, nocturnal enuresis is twice more common in boys than girls but thereafter there is no gender difference.⁶ Among functional voiding disorders, OAB is commoner (68.2%) than DV (19.5%).⁷ Among children with voiding disorders, the common symptoms are urgency (49.7%), holding maneuvers (42.1%), diurnal incontinence (20.1%), straining (16.6%), altered urinary frequency (10.9%), dysuria (5.9%) and constipation (3.1%).⁸

PATHOPHYSIOLOGY

Monosymptomatic Enuresis

Combinations of various factors are implicated in the etiology.⁹

Developmental and Behavioral Factors

Children with delayed milestones may delay in achieving dryness. Voiding disorders are more common among chil-

dren with neuropsychiatric disturbances, such as attention deficit hyperactivity disorder (15%).¹⁰

Genetics

Genetic loci on 8q, 12q and 13q and ENURI 1 gene has been identified on the long arm of chromosome.¹³ The mode of inheritance appears to be autosomal dominant with reduced penetrance.¹¹ The odds ratios for nocturnal enuresis is 3.63 times higher in maternal and 1.85 times higher in paternal nocturnal enuresis.⁵

Nocturnal Inappropriate Antidiuretic Hormone Activity

Antidiuretic hormone (ADH) has a peak secretion between 4 and 8 AM. Lack of circadian rhythm or impaired response of the kidneys to ADH contributes to enuresis.^{9,12}

Bladder Capacity

The maximal voided volume (MVV) of the bladder is reduced in children with enuresis.¹³ The term functional bladder capacity has been replaced by MVV to avoid confusion.³ Maximal voided volume is the same as expected bladder capacity (EBC) which is obtained by the formula $EBC = (30 + (\text{age in years} \times 30))$ in ml.

Sleep Factors

Enuretic children have high arousal thresholds¹² due to underlying brainstem abnormalities, or paradoxically raised by repeated arousal stimuli of the bladder distension. The locus coeruleus (LC), a noradrenergic neuron group in the upper pons is crucial for arousal from sleep. It overlaps both functionally and anatomically with the pontine micturition center and also has axonal connections with the hypothalamic cells that produce vasopressin. Thus a disturbance in this important junction is implicated in enuresis.⁹

Obstructive Airway Disease

The constant arousal stimuli from obstructed airways cause paradoxically high arousal thresholds. Brain natriuretic peptide (BNP) levels increases with snoring and airway obstruction thus aggravating polyuria.^{9,14}

Non-monosymptomatic Enuresis or Functional Voiding Disorders

The basic abnormality in children with Functional voiding disorders (FVD) is abnormal pelvic floor and detrusor contractions.¹⁵ (Fig. 2). Additional factors that aggravate FVD are early initiation of toilet training and constipation (48%).¹⁶ The association of constipation with FVD is termed dysfunctional elimination syndrome.¹⁷ The pathophysiology and progression of FVD is depicted in Flow chart 1.³ The pathophysiology of enuresis (both mono-

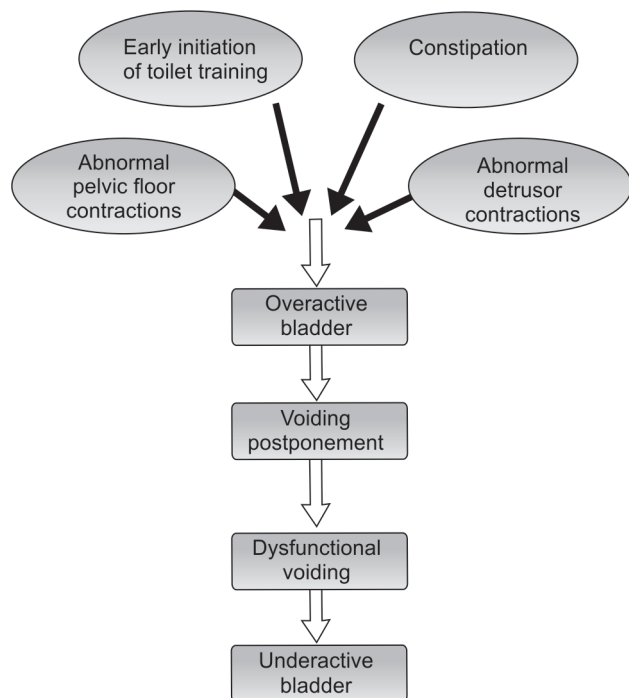

Fig. 2: Plasticity theory describes the role of abnormal pelvic floor and detrusor contraction in evolution of FVD

Flow chart 1: Pathophysiology and progression of functional voiding disorders

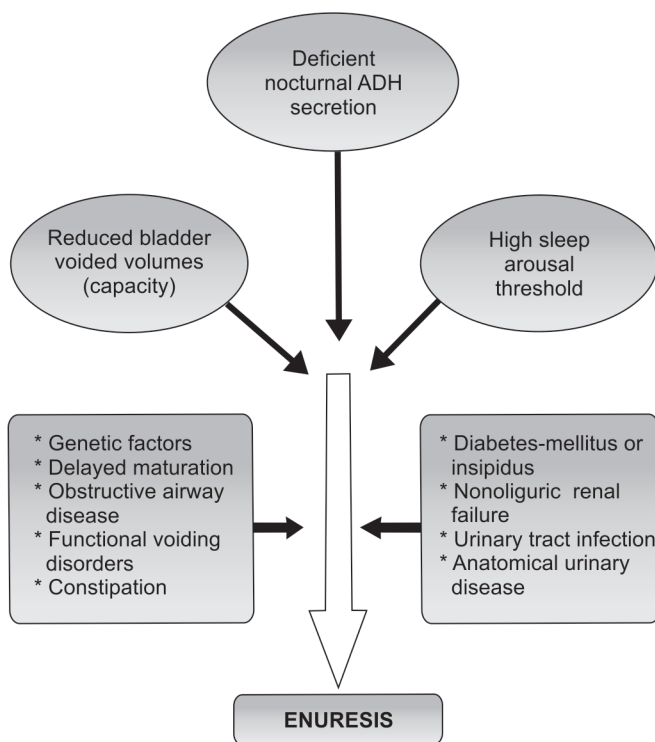

symptomatic and non-monosymptomatic) is described in Flow chart 2.

Anatomical Causes for Incontinence

Extrophy of the bladder, epispadias and urethral trauma are obvious causes for incontinence. However, ectopic ureters, urogenital sinus anomalies and posterior urethral valves require proper imaging and a cystoscopic evaluation for diagnosis. Those boys with urethral valve malformation not

Flow chart 2: Pathophysiology of monosymptomatic and non-monosymptomatic enuresis

only have a disturbed bladder function but also renal tubular damage that leads to vicious circles of polyuria, increased intravesical pressure and yet more renal damage.⁹

Neurogenic Bladder

Spinal dysraphism, closed or open menigomyelocele, sacral agenesis, autonomic neuropathy, transverse myelitis, spinal trauma, tumors or degenerative disorders of the spine may develop a neurogenic bladder.

Other causes

- Diabetes—mellitus or insipidus
- Non-oliguric renal failure
- Urinary tract infection

APPROACH TO A CHILD WITH A VOIDING DISORDER

Urinary incontinence has a strong social stigma recognized by children as the third most stressful situation in life after death of a parent and going blind.¹⁸ Therefore an understanding and a systematic approach is advised to these children.

History

A detailed history of voiding and bowel habits should be noted. The clinical features and their inference is

described in Table 1. A child may also demonstrate the Vincent’s curtsy (a typical position wherein the child bends forward or sits on the floor with the heel of a folded leg tucked into the perineum), to increase the external sphincter tone during bladder contractions. The Farhat scoring system is a reliable screening tool in the identification of FVD¹⁹ (Table 2).

Clinical Examination

It should include growth assessment, blood pressure, abdominal and genital examination. It should also include a detailed neurological evaluation, anal sphincteric tone and gait evaluation. The lower back should be examined

for tuft of hair, spinal dysraphism and scars of operated meningocele. The psychological state of the child should be noted. It is worthwhile to note that a distressed child is also motivated for therapy.

Frequency Volume Charting

A meticulous record of the number of times a child voids and the volume of each voiding is recorded for at least 48 hours.³ Abnormal patterns of voiding such as small quantity day time frequent or infrequent voiding may be noted which otherwise may not be forthcoming in the initial history. An abnormal frequency volume charting strongly suggests an underlying FVD.

Table 1: Relevant patient history to be noted in a child with a voiding disorder

Areas of interest	Relevance
General health and development	
Growth, weight loss	Poor growth in renal failure. Malaise, nausea, weight loss, etc. in diabetes or kidney disease
<i>Micturition and drinking habits</i>	
Bedwetting frequency	Prognosis poor in higher frequency enuresis
Previous dryness	Comorbidity (somatic or psychiatric) more common in secondary enuresis
Daytime incontinence: When? How often?	Neurogenic or anatomic causes gives daytime incontinence more often than isolated enuresis.
Urgency	Indicates overactive bladder
Weak stream, hesitancy, straining	Indicate dysfunctional voiding neurogenic bladder
Urinary tract infections	Indicates FVD (Overactive bladder or dysfunctional voiding)
Excessive thirst. Need to drink at night	Kidney disease, diabetes or habitual polydipsia.
Bowel habits	
Constipation	Dysfunctional elimination syndrome
Encopresis	Most commonly caused by constipation.
Psychology	
Behavioral problems	Risk for therapy-resistance and/or psychiatric comorbidity. Consider parallel psychological evaluation.
How does the child view his/her enuresis?	The child who is not bothered by the enuresis may not be motivated for labor-intensive therapy

Table 2: The investigations, the typical features and their inference in a child with a voiding disorder

Investigation	Abnormality Detected	Inference
Urine analysis		
Urine biochemistry	Glucosuria	Consider diabetes mellitus. Check blood glucose
	Proteinuria (++ or more on urine test)	Consider kidney disease
Urine microscopy	Significant pus cells positive	Take urine culture. Consider UTI

Contd...

Contd...

Ultrasonography		
Bladder	Thick bladder wall *	Underactive bladder Neurogenic bladder Bladder outflow obstruction
	Significant postvoid residue †	Incomplete voiding Vesicoureteric reflux (VUR)
Pelvic/ureteric system	Bladder wall irregularity	Recurrent UTI /Cystitis
	Hydroureteronephrosis	Obstructive uropathy /VUR
Kidneys	Anomalies (Duplication /absence)	Anatomical anomalies
	Small shrunken kidney(s)	Chronic renal disease
	Enlarged kidneys	Hydronephrosis
	Calculi/ Nephrocalcinosis	Obstructive uropathy
Micturating cystourethrogram		
Urinary bladder	Bladder wall irregularity	Overactive bladder
	Elongation of the bladder shape	Dysfunctional voiding
	Filling of the posterior urethra	Neurogenic bladder
	Spinning top configuration of the bladder	
	Small sized bladder with multiple trabeculations (Christmas tree appearance)	
Radiograph and MRI of spine		
Lumbosacral spine	Spinal dysraphism, Diastomatomyelia, Spinal trauma, tumors Degenerative disorders	Neurogenic bladder

* Upper limit for detrusor thickness of ventral wall of urinary bladder at all ages is 2.0 mm at 50% bladder fullness or 1.5 mm at a higher degree of fullness

† Bladder volumes of ≥ 20 ml, or $>10\%$ of the cystometric bladder capacity.

Investigations

The only investigation required in monosymptomatic enuresis is a urine analysis to look for Urinary tract infection (UTI), glucosuria and proteinuria. In non-monosymptomatic enuresis, suspected neurogenic bladder and anatomical anomalies, further investigation with ultrasonography of the kidneys, ureters and bladder (USS), micturating cystourethrogram (MCU) and radiograph of the spine are only required. In certain cases magnetic resonance imaging (MRI) of the spine may be required to look for neurological defects. A frequency volume chart, USS and MCU are together labeled as “Noninvasive urodynamic studies”.¹⁷

Noninvasive assessment of the urinary bladder is fairly accurate in predicting the underlying bladder dysfunction. Nocturnal enuresis with day time symptoms, holding maneuvers, small frequent voiding pattern and a small capacity bladder with insignificant residue and elongation of bladder neck in pre-micturition film on MCU predicts OAB. Straining, recurrent UTI, infrequent voiding, large capacity bladder with significant postvoid residue in the absence of a VUR and a spinning top bladder on an MCU predicts DV.⁷

Invasive urodynamic studies are indicated only in cases where the diagnosis is unclear or response to therapy is poor. The investigations, the typical features and their inference are listed in Table 2. The algorithmic approach to a child with a voiding disorder is depicted in Flow chart 3 and 4.

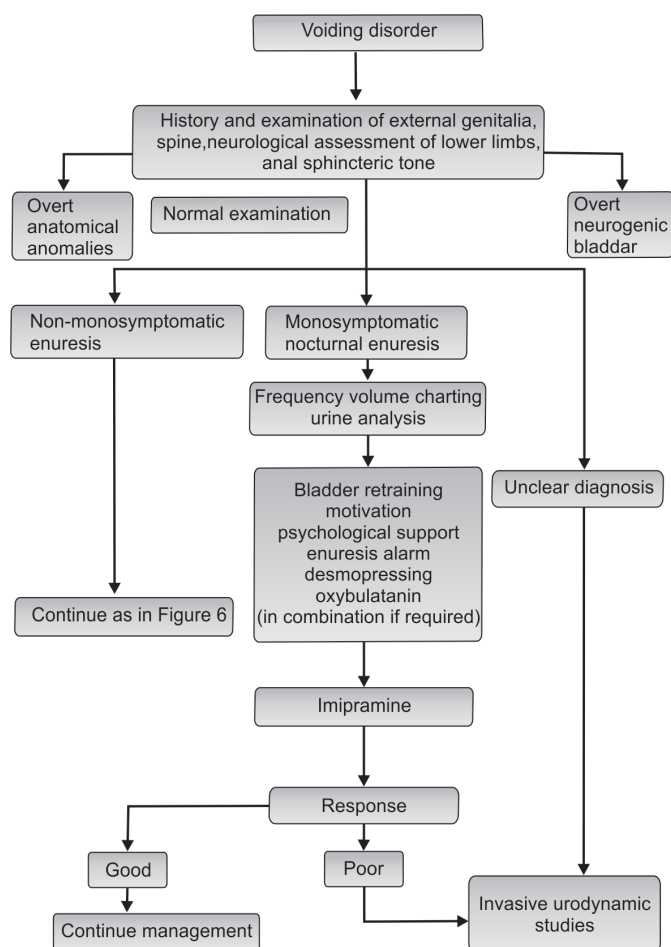

TREATMENT

The therapeutic plan needs to be discussed with the parents and individualized to the child's needs.

Monosymptomatic Enuresis

Regulated oral fluid intake: There is limited role of withholding fluids in the evening, random awakening of the child to void or punitive measures.²⁰ However, diuretic drinks like tea, coffee and sodas should be avoided in the evening.

Motivational therapy: The child is reassured, provided emotional support and every attempt is made to remove any feeling of guilt. Dry nights merit praise and encouraging words from the parents.²¹

Flow chart 3: Algorithmic approach to a child with voiding disorder

Enuresis alarm

This involves the use of an alarm device to elicit a conditioned response of awakening to the sensation of a full bladder and gradually the association with bladder distention evokes micturition. The alarm device consists of a small sensor attached to the child's underwear, or a mat under the bed-sheet and an alarm attached to the child's collar or placed at the bedside. When the child starts wetting the bed, the sensors are activated causing the alarm to sound. The therapy should continue until 14 consecutive dry nights have been achieved.

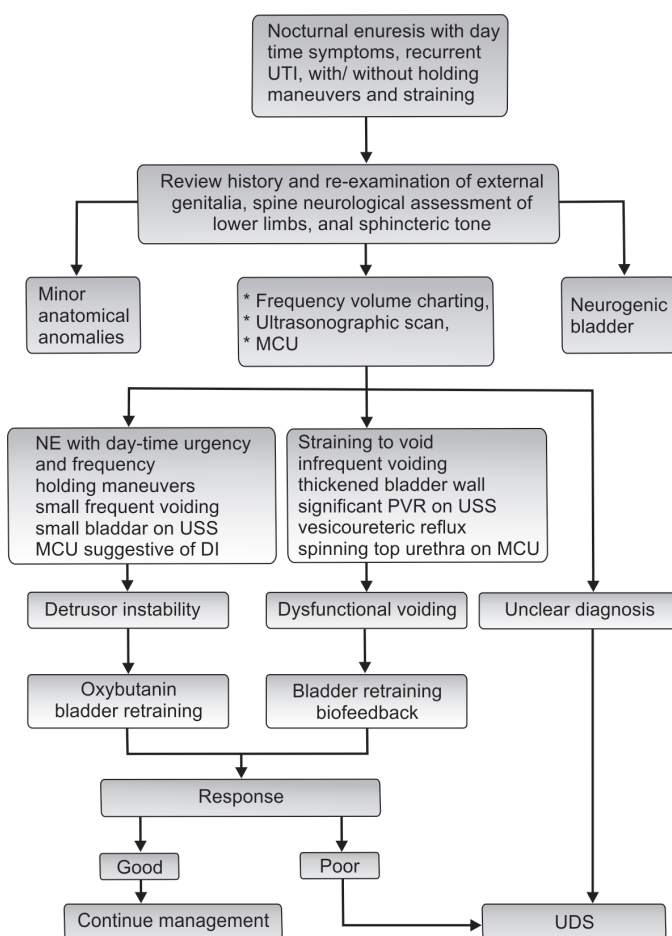

Pharmacotherapy

The common drugs used in the treatment of voiding disorders, their mechanism of action, dose and side effects are summarized in Table 3.⁹

Non-monosymptomatic Nocturnal Enuresis

Non-pharmacological therapy

Behavioral intervention: This consists of patient education, scheduled voiding regimen with gradual increasing

Flow chart 4: Algorithm to manage a case of functional voiding disorder, NE= Nocturnal Enuresis

intervals, urgency control strategies, self-monitoring and positive reinforcement. Initially the child is asked to void every two hours and gradually the voiding intervals are increased. Pelvic floor and bladder exercises with biofeedback are very useful.²²

Pharmacotherapy

Correction of constipation: Isabgol husk, lactulose and PEG-3350 (polyethylene glycol 3350) powder may be used. It is important to treat constipation consistently for 3 to 6 months.

Treatment of UTI: Judicious use of antibiotics guided by sensitivity reports is essential to control infections. Antibiotic prophylaxis may be required in children with recurrent UTI and with large postvoid residues.

Anticholinergic agents: In children with the urge syndrome and detrusor instability an anticholinergic medication like oxybutinin and tolteridone can be effective. (Table 4) Tolteridone is better tolerated than Oxybutanin.²³

Table 3: Medications used in treatment of nocturnal enuresis, their doses and side effects

Medication	Mechanism of action	Dose	Duration of use	Age group	Side effects	Precautions
<i>Desmopressin</i>	Vasopressin analog exerting ADH action	Oral – 120-240 μ g/day Nasal spray – 10-40 μ g/day	4 weeks dry and then tapered off over 3 weeks	Any	Hyponatremia, nasal stuffiness, headache, epistaxis, abdominal pain, nausea	Limit fluid intake to 200 ml from 1 hour before medication until the next morning.
<i>Oxybutanin</i>	Anticholinergic	10-20 mg/day	3-6 months	> 6 years	Dryness of mouth, facial flushing, palpitations, constipation and blurring of vision	Adequate oral fluids and prevent constipation
<i>Tolteridone</i>	Anticholinergic	2-4 mg/day 1 hour before bedtime	3-6 months	Any	Same as Oxybutanin but less intense	
<i>Imipramine</i>	Antipsychotic Anticholinergic	25-50 mg/day PO 1 hour before bedtime	3-6 months and gradually tapered	> 7 years	Anxiety, mood disturbances, personality change and palpitations	ECG to rule out long QT syndromes is mandatory. 2 weeks off medication every 3 months to prevent tolerance
<i>Doxazosin</i>	Alfa blocker	0.5-1 mg/day	3-6 months	> 6 years	Headache, fatigue, dizziness hypotension	Blood pressure monitoring

Alpha-blockers

Doxazosin (0.5 to 1 mg/day) may be used in dysfunctional voiding along with biofeedback. (Table 170.4)²⁴

Surgical intervention

In children with established dysfunctional voiding with large post void residues it is imperative to lower intravesical pressures in order to protect the upper tract. Clean intermittent catheterization (CIC) can be instituted with training.²⁵ A Mitrofanoff conduit can aid CIC especially in girls attending school.²⁶

COMPLICATIONS

The following complications in untreated children with voiding disorders are noted:

- Psychosocial complications¹⁸
- Recurrent UTI²⁷
- Hydrouretronephrosis
- Renal parenchymal damage and failure

PROGNOSIS

In monosymptomatic enuresis success rates up to 82 percent and 77.8 percent are seen with enuresis alarms and DDAVP respectively. The recurrence rates are much higher with DDAVP and imipramine.²⁸ In FVD, 94 percent show

improvement in recurrent UTI and 76 percent in voiding symptoms. The onset of VUR and renal dysfunction heralds a poorly reversible situation. The improvement in VUR and renal parameters are seen only in 63 percent and 37 percent respectively.²⁹ This fact highlights the need for timely intervention in these children.

INTRODUCTION

The term “urolithiasis” refers to the formation of stones within the kidneys or urinary tract. “Nephrocalcinosis” is the presence of calcium deposits within the parenchyma of the kidney. Since both conditions can occur due to the same set of etiologies, they are usually discussed together.

The incidence of renal stones is thought to be rising in industrialized countries, and is estimated to occur in about 5 percent of population.¹ In children, although exact figures are unavailable particularly in the Indian subcontinent, incidence rates are only approximately 10 percent of adult rates. The reason for this much lower rate is thought to be due to the increased presence of inhibitor substances in pediatric urine.² However, several genetic and metabolic conditions typically present in the pediatric age group and require early diagnosis and treatment, to prevent multiple bilateral and recurrent stone disease or progressive nephrocalcinosis and urolithiasis which can lead to renal failure.

Calcium oxalate is the most common renal stone worldwide, and accounts for 60 to 90 percent of pediatric urolithiasis. Calcium phosphate accounts for 10 to 20 percent, uric acid for 5 to 10 percent, struvite for 1 to 18 percent of stones in developed countries, cystine for 1 to 5 percent and mixed or miscellaneous 4 percent of the pediatric stones.³

ETIOLOGICAL FACTORS

Calcifications in the urinary tract occur when there is supersaturation of solutes in urine leading to crystal deposition. This can occur due to absolute solute excess or due to reduced solvent. Urinary tract obstruction and congenital anomalies that lead to stasis and poor urinary flow are also risk factors. Urine infection can be both the precipitating cause and the sequel of renal stones. In many conditions

Table 1: Etiology of nephrocalcinosis/urolithiasis

| 5. | <i>Infection</i> |

more than one factor may be present and may be associated with a deficiency of stone inhibiting substances. The different etiopathologies of urolithiasis and nephrocalcinosis are described in brief below²⁻⁴ and tabulated in Table 1. Seventy-five percent of children have an identifiable predisposing cause of which metabolic causes are 33 percent, structural anomalies 32 percent and infection 4 percent.²

Metabolic Conditions

Hypercalciuria

The most common cause of pediatric renal stones is hypercalciuria which accounts for over 50 percent of metabolic etiologies.² This can be caused by excessive calcium and

vitamin D supplements, dietary salt and protein excess or phosphate deficiency, by drugs such as steroids and frusemide, or by prolonged immobilization. It may be associated with hypercalcemia as in hyperparathyroidism. Hypercalciuria may be transmitted in families as a polygenic or as an autosomal dominant trait. Several rare genetically transmitted renal tubular disease are associated with hypercalciuria and include familial hypomagnesemia with hypercalciuria, renal tubular acidosis, neonatal Bartter's syndrome, Dent's disease and Lowe's syndrome. Very often, however, no specific cause can be found, and it is termed "idiopathic".

Hyperoxaluria

Hyperoxaluria accounts for 2 to 20 percent of metabolic urolithiasis. Oxalate rich foods include rhubarb, beets, okra (bhindi), spinach, berries, nuts, sweet potatoes (shakarkandi), tea, chocolate and soy products. Excessive dietary intake of these substances may result in renal stones. Acute oxalate nephropathy is seen in ethylene glycol poisoning which occurs in cold countries where it is a component of car antifreeze agents. Loss of gut colonization by oxalate degrading anaerobic bacteria (e.g. *Oxalobacter*) may result in increased oxalate absorption, leading to hyperoxaluria and stone formation.⁵ Enteric hyperoxaluria occurs in gastrointestinal malabsorptive states, where excess fats in the intestine bind with calcium leaving oxalate behind for systemic absorption.

Primary or genetic hyperoxalurias are rare autosomal recessive inherited diseases that cause marked hyperoxaluria. They are due to deficiency of hepatic enzymes—alanine glyoxylate aminotransferase (AGT) or glyoxylate reductase/hydroxypyruvate (GRHPR) reductase. These conditions cause early and progressive nephrocalcinosis and recurrent stones and lead to extensive renal damage. Subsequent to renal impairment, lack of excretion leads to very high levels of oxalate in the blood—termed oxalosis, which causes damage to many body organs.

Hyperuricosuria

Increasingly, uric acid stones are occurring in obese adolescents with the metabolic syndrome and in children with high protein diets. This is a component for the growth of renal stone disease in industrialized countries. The condition may be familial or idiopathic. It may arise due to drugs such as probenecid, phenylbutazone, salicylates and pancreatic extracts used in cystic fibrosis. Severe hyperuricosuria and renal stones occur in genetic diseases such as Lesch-Nyhan syndrome and phosphoribosyl pyrophosphate synthetase superactivity. It is also seen in conditions where there is increases cell turnover like tumor lysis syndrome, lympho-or myelo-proliferative disorders.

Cystinuria

Cystinuria is the cause of 2 to 8 percent of metabolic stone disease in children. This is an autosomal recessive condition, in which renal tubular reabsorption of cystine and the dibasic amino acids, i.e. ornithine, arginine and lysine is defective, and they are lost in the urine. Cystine is poorly soluble in urine with pH of 7 or less. There are 3 disease types involving 2 genes, with type 1 being the most severe, affecting even infants. It is associated with early, bilateral and recurrent renal stones that can result in renal failure if untreated.

Deficiency of Stone Inhibitors

There are several substance that are present in urine and act as inhibitors of urinary crystallization. Hypocitraturia is present in several diseases where stone formation occurs, like renal tubular acidosis, and hypokalemic conditions. Other urinary inhibitors are magnesium (as in familial hypomagnesemia with hypercalciuria), and pyrophosphate. Other inhibitors under study include glycosaminoglycans, osteopontin, and nephrocalcin.

Environmental, Dietary and Geographic Factors

There is a great difference in incidence of renal stones depending on race, environment and diet.⁶ Urinary bladder stones are endemic in certain "stone belts"—an example being the dry north western states of India. A combination of factors, namely, hot and dry environment with scarcity of drinking water and a diet low in animal protein but rich in cereals are contributing factors. Excessively high protein diets and ketogenic diets used in epilepsy are also associated with increased risk of urolithiasis. Additionally, excessive intake of sodium, calcium and oxalate can result in renal stones.

Congenital Malformations, Stasis and Infection

Conditions interfering with the flow of urine in the renal tract are risk factors for formation of crystals due to stasis and for infection. The most common conditions are medullary sponge kidney and autosomal dominant polycystic kidney disease which are usually diagnosed in adulthood. Pediatric renal malformations can also be associated with stone formation, like hydronephrosis and horse shoe kidneys. Stasis is often associated with infection which is an additive risk factor. Bladder augmentation using intestinal mucosa is a risk factor for bladder stones.

Several bacteria (*Proteus*, *Klebsiella*, *Pseudomonas*, *Ureaplasma*, etc.) have an enzyme called urease which hydrolyses urea to form ammonium and bicarbonate ions in urine. The resulting alkaline pH causes phosphate dissociation and formation of magnesium ammonium phosphate stones which are called struvite and can result in large staghorn calculi which grow rapidly and are difficult

to remove. Xanthogranulomatous pyelonephritis which is a serious kidney infection that can lead to renal failure may be associated with staghorn calculi.

Certain Conditions which are Associated with Urolithiasis

Prematurity in itself is a risk factor for nephrocalcinosis and renal stones. This risk is compounded by treatment with steroids, frusemide and TPN. Patients with spinal dysraphism have poor bladder function and recurrent infection and this compounded by relative immobilization may be a risk for urolithiasis. Gastrointestinal diseases and obesity are also risk factors as mentioned above.

Miscellaneous

Several drugs are associated with urolithiasis and include the antiretroviral agent—idinavir, and others such as ceftriaxone, sulfonamides, etc. The treatment of gout with allopurinol can result in xanthine and hypoxanthine stones.

CLINICAL HISTORY AND EXAMINATION

The common symptoms of renal stones are colicky abdominal pain and hematuria.^{2,7} The characteristic “renal colic” that occurs in adults with pain radiating from the flanks to the groin, is rare in young children who more commonly complain of diffuse nonspecific abdominal pain. Macroscopic painful hematuria mandates a search for renal stones. Stones in the bladder or urethra can present with dysuria, frequency of urination, and urinary retention. Urethral stones may be palpable in boys. Symptoms of UTI may be present with fever. However, stones and particularly nephrocalcinosis are often silent and picked up on investigation in the presence of risk factors such as family history or congenital structural renal anomalies. They may be detected during screening of patients with associated conditions such as UTI, Fanconi’s syndromes, RTA, Dents disease and Bartter’s syndrome.

Once stones or nephrocalcinosis is detected, it is important to ask about family history since many conditions in the pediatric age group are genetically transmitted. Details of diet, drinking behavior, usual climate and history of immobilization or prematurity and UTI should be sought. Drug intake including frusemide, calcium, vitamin D analog, steroids, allopurinol may be causative factors. Any known associated renal or GIT disorder or congenital renal malformation should be investigated.

In patients with secondary renal stones there may be short stature, failure to thrive, dehydration, hyperventilation and rickets. Renal parenchymal damage may be associated with hypertension, anemia and metabolic bone disease. Characteristic stigmata may be present in syndromes such as Lesch-Nyhan syndrome and Lowe’s syndrome.

INVESTIGATIONS

The aim of the diagnostic process is not only to: (1) accurately define the presence and location of urinary stones or nephrocalcinosis, but also to (2) detect any adverse effects such as UTI, obstruction causing proximal dilatation or renal functional impairment and (3) to diagnose or exclude a treatable causative factor such as infection, stasis, obstruction, structural anomaly of the renal tract or underlying metabolic disease. Imaging modalities utilizing the minimal amount of radiation are preferred and the ultrasound scan has become the most utilized tool (Figs 1A to D). However in a few cases where stones are small and situated in the renal papillae or ureters, USS may not detect them and in such cases CT is the most sensitive (Fig. 2).

Imaging Modalities

Ultrasound (US)

The US is the most commonly used tool for the diagnosis and further monitoring of renal stone disease. Nephrocalcinosis appears as echogenic foci in the renal parenchyma. It most commonly affects the medulla, but may be cortical or diffuse in distribution. Isolated renal cortical calcinosis may be seen after renal cortical necrosis. Medullary nephrocalcinosis is further classified radiographically by the distribution and the density of deposits as Grade I—with mild increase in echogenicity around the border of the medullary pyramids; Grade II—with mild diffuse increase in echogenicity of the entire medullary pyramid; Grade III—with a greater, more homogeneous increase in the echogenicity of the entire medullary pyramid.⁸

Stones are detected on ultrasound as echogenic areas with a distal “acoustic shadow”, i.e. a line of hypoechogenicity where the sound waves are not transmitted as they are blocked by the solid stone material. The USS is good at detecting renal and bladder stones but poor at detecting ureteric stones particularly small ones.

The USS also provides important information regarding whether there is any obstruction of the renal system, or any structural anomaly. Being nonradiating it can be used easily for serial studies to monitor progress. However a limiting factor is its subjectiveness particularly where monitoring for changes in stone size is concerned.

Plain X-ray

A plain abdominal X-ray of a properly prepared child (after adequate bowel clearance) can reveal stones in the renal tract if the stones are radiopaque. Most stones containing calcium and dense nephrocalcinosis will be radiopaque, and include calcium oxalate and calcium phosphate stones. Struvite and cystine stones are of intermediate density. Uric acid stones are radiolucent and cannot be detected without administration of contrast. Small stones of any variety may be missed on X-ray.

Figs 1A to D: Ultrasound scans; (A) Normal kidney; (B) Nephrocalcinosis; (C) Renal stone; (D) Ureteral stone with proximal dilatation

Fig. 2: Non-enhanced CT scan showing uric acid stone in left lower ureter near ureterovesical junction, which was not identified on US

Intravenous Urogram (IVU)

IVU was very popular for detecting stones prior to the widespread availability of ultrasound scans. They show even radiolucent stones as filling defects and are particularly good for determining the exact site of the stone related to the urinary tract and the presence or absence of proximal dilatation. However, the large radiation dose involved due to the repeated films and the risk of contrast nephropathy have greatly limited the use of this modality particularly when sufficient information is obtained by US.

CT Abdomen

The noncontrast CT scan is a sensitive modality for the detection of small ureteric stones. The limiting factor is the associated radiation and it is reserved for special situations where the index of suspicion is high but US is not helpful.

DTPA/MAG3 Scans

These isotope scans cannot detect stone, but are used to monitor degree of obstruction and individual renal function.

Blood and Urine Examination

Since a large proportion of children have underlying metabolic causes of stone formation, a blood and urinary stone profile should be sent. This is most important if there is family history or if the involvement is bilateral, multiple and recurrent. As screening tests, spot urinary values using solute—creatinine ratios are useful. However, since values may differ with time, diet and age, suspicious findings should be confirmed with 24 hour urinary collections, or when that is difficult using timed urinary collections. Normal values are given in Table 2.

The metabolic stone profile includes:

Blood for—urea, creatinine, electrolytes, bicarbonate, calcium, phosphate, magnesium and uric acid.

Urine is tested for—pH, osmolarity, creatinine, calcium, magnesium, phosphate, oxalate, cystine, urate, citrate. Urine should be checked microscopically for RBC's, pus cells and any typical crystals and a culture should be included to exclude infection. If stones are passed, these should be collected and analyzed. Infrared spectroscopy or X-ray diffusion methods are superior to chemical analysis.

MANAGEMENT

General Management

There are certain measures that in general reduce stone formation,^{2,7} and these are: (1) maintain good hydration and good urine flow with adequate fluid intake and early treatment of any obstructive urological lesion (2) early detection and control of urinary tract infection (3) low salt diet—sodium and calcium share common sites for reabsorption in the renal tubules and restricting sodium intake encourages calcium reabsorption, thus reducing hypercalciuria. Excesses of dietary calcium, oxalate and protein beyond RDA should be avoided. (4) Inhibitors of stone formation include citrate, potassium and magnesium, supplements. (5) the use of alpha adrenergic antagonists and calcium channel blockers by relaxing urethral smooth muscle have recently been tried for urethral stones in adults⁹ (6) avoid immobilization.

Stones that are less than 5 mm in diameter and not associated with obstructive changes usually do not require removal as they may pass through the urinary tracts and can be excreted. Larger stones need removal particularly if they are associated with symptoms such as pain or swelling or obstruction detected on USS or IVU. The options for stone removal are:

- **ESWL:** Extracorporeal shock wave lithotripsy can be used for fragmentation of stones that are less than 1 to 2 cm, with normal renal function, no infection and favorable anatomy. Reduction in stone size enables excretion through the urinary tract. Although there are concerns regarding the consequence of this therapy on the developing kidneys, with proper case selection the process is reported to be safe and effective.¹⁰

Table 2: Normal values of urinary excretion of different solutes^{2,8}

Solute	Age group	Solute/creatinine ratio	Timed excretion
Calcium	<6 months	<0.8 mg/mg	<4 mg/kg/24 hours
	7–12 months	<0.6 mg/mg	
	>2 years	<0.21 mg/mg	
Oxalate	<1 year	0.15–0.26 mg/mg	>2 years: <45 mg/1.73 m ² /24 hours
	1–5 years	0.11–0.12 mg/mg	
	5–12 years	0.006–0.15 mg/mg	
	>12 years	0.002–0.083 mg/mg	
Cystine		<75mg/g	<60 mg/1.73 m ² /24 hours
Uric acid	0–1 year	<2.2	<815 mg/1.73 m ² /24 hours
	1–3 years	<1.9	
	3–5 years	<1.5	
	5–10 years	<0.9	
	>10 years	<0.6	
Citrate		>180–400 mg/g	
Magnesium	>2 years	≥0.12 mg/mg	≥88 mg/1.73 m ² /24 hours

- *Surgical removal:* Lower ureteric, bladder and urethral stones may be removed by a variety of urethro-cysto-uretero-scopic maneuvers. Stones in the upper urinary tracts require nephrostomies for clearance by open or per-cutaneous methods. Particularly in metabolic conditions where recurrence is common, repeated surgical procedures can cause renal parenchymal or ureteral muscle damage.^{10,11}

Specific Management

Specific metabolic conditions require specific therapies which need to be urgently instituted to prevent progress,

Table 3: Specific management of metabolic urinary stone disease

Hypercalciuria	<ul style="list-style-type: none"> • Avoid immobilization • Low sodium diet • Avoid excess calcium or vitamin D intake • Correct deficiencies of potassium and phosphate • Stop causative drugs (frusemide/steroids) if possible • Correct hypercalcemia if present • Correct acidosis if present • Thiazide diuretics
Hyperoxaluria	<ul style="list-style-type: none"> • Avoid foods rich in oxalate • Treatment of fat malabsorption (low fat diet, bile acid sequestrants) • Treatment with oxalate degrading bacteria under trial • In genetic hyperoxalurias: <ul style="list-style-type: none"> – Pyridoxine – Early intensive hemodialysis if renal insufficiency – Liver transplant replenishes enzyme defects – Combined liver and kidney transplant if ESRD.
Hyperuricosuria	<ul style="list-style-type: none"> • Avoid excess protein intake • Maintain urinary pH above 7.0 • Allopurinol
Cystinuria	<ul style="list-style-type: none"> • Very high fluid intake • Maintain urinary pH above 7.5 • α-Mercaptopropionylglycine or penicillamine
Struvite	<ul style="list-style-type: none"> • Treat UTI • Remove stasis producing factors

new stone formation and ensuing renal damage.^{4,9} These are summarized in Table 3.

CONCLUSION

Although urolithiasis and nephrocalcinosis are rare in childhood, they can be recurrent and progressive, and are often due to underlying metabolic or structural defects. All affected children therefore, need a detailed diagnostic evaluation to look for causative factors. Several non-invasive and minimally invasive methods are now available for the removal of stones that cause symptoms, UTI or obstruction. Medical management includes general measures of mobilization, hydration, analgesia, treatment of UTI and supplementation with various crystal inhibitors. Specific therapy is aimed at the management of any specific etiological factor that is diagnosed followed by close monitoring with aim to prevent recurrence or progression.

Hereditary Nephropathies

PK Pruthi, Kanav Anand

INTRODUCTION

Hereditary renal disorders are an important cause of chronic kidney disease in children. This group includes a variety of disorders like:

- Alport syndrome
- Thin basement membrane disease
- Polycystic kidney disease
- Nephronophthisis—medullary cystic disease complex
- Cystinosis
- Nail patella syndrome
- Lowe syndrome.

ALPORT SYNDROME

Alport syndrome (hereditary nephritis) is an inherited progressive form of glomerular disease that is often associated with sensorineural hearing loss and ocular abnormalities¹. This syndrome is a primary basement membrane disorder arising from mutations in genes encoding several members of the type IV collagen protein family. These alpha IV collagen chains are normally located in various basement membranes of the kidney, cochlea and eye.

Genetics

Transmission of Alport syndrome can be X-linked, autosomal recessive or autosomal dominant. X-linked transmission accounts for approximately 80 percent of affected patients and arises from mutations in the *COL4A5* gene on the X chromosome. Autosomal recessive variant is responsible for about 15 percent of patients with Alport syndrome and arises from genetic defects in either the *COL4A3* and *COL4A4* genes while, autosomal dominant disease occurs in about 5 percent of patients with Alport syndrome and arises from heterozygous mutations in the *COL4A3* or *COL4A4* genes.

Clinical Manifestations

The course of Alport syndrome is gender and genetic transmission dependent. Males with X-linked or recessive forms of the disease are at high-risk for progression to end stage renal disease. Females and those with the autosomal dominant form do better and show less rapid progression.

The clinical manifestations vary according to the system involved:

- *Renal manifestations:*¹
 - Asymptomatic persistent microscopic hematuria (onset is usually below 10 years of age).
 - Recurrent episodes of gross hematuria, which usually follows upper respiratory tract infections.
 - Proteinuria, hypertension and progressive renal insufficiency can develop over a period of time.
 - End stage renal disease (ESRD) usually occurs between the ages of 16 and 35 years in patients with X-linked or autosomal recessive disease.

The Alport nephropathy progresses through a series of clinical phases. Phase I typically lasts from birth until late childhood or early adolescence and is characterized by isolated hematuria, with normal protein excretion and renal function. In Phase II, proteinuria is superimposed on hematuria but renal function remains normal. Patients in Phase III exhibit declining renal function in addition to hematuria and proteinuria, and those in phase IV have ESRD.

- *Hearing loss:*²
 - Bilateral sensorineural hearing loss is usually in the range of high frequency to begin with and later it progresses over time to frequencies in the range of conversational speech. In general, the rate of hearing loss is similar to the progression of renal insufficiency.

- *Ocular manifestations:*^{3,4}
 - Lens — Anterior lenticonus occurs in 20 to 30 percent of males with X-linked Alport syndrome and is pathognomonic of the disease.
 - Retina — Bilateral white or yellow granulations that are superficially located in the retina surrounding the foveal area (known as Dot-fleck retinopathy) are specific for Alport syndrome.
 - Cornea — Posterior polymorphous dystrophy and recurrent corneal erosions are observed sometimes.
- *Leiomyomatosis:* Leiomyomas may be found within the respiratory, gastrointestinal and female reproductive tracts.⁵
- *Arterial disease:* Aneurysms of the thoracic and abdominal aorta are occasionally associated features.
- *Others:* Alport syndrome may be associated with abnormal platelet numbers and size, hyperprolinuria, hypoparathyroidism, midface hypoplasia and cerebral dysfunction.⁶

DIAGNOSIS

Although the possibility of Alport syndrome is generally suspected from the family history of renal failure and deafness,⁷ the diagnosis is usually confirmed by a skin or renal biopsy. In a renal biopsy specimen, the characteristic finding of longitudinal splitting of the lamina densa of the glomerular basement membrane (GBM) detected by electron microscopy is diagnostic for Alport syndrome. Light microscopy findings include mesangial matrix expansion

with segmental proliferation, presence of lipid laden foam cells and irregular thickening of capillary walls. Immunostaining of type IV collagen demonstrates absence or an abnormal distribution of the alpha-3, alpha-4 and/or alpha-5(IV) chains of the GBM.

In recent times, molecular genetic testing is being used to diagnose Alport syndrome and it may eventually become the diagnostic procedure of choice because it is noninvasive and can be extremely accurate.⁸

DIFFERENTIAL DIAGNOSIS

Other glomerular disorders that present in children with microscopic hematuria include IgA nephropathy and thin basement membrane nephropathy. Megathrombocytopenia (thrombocytopenia with large or giant platelets) has been described in some families with autosomal dominant hereditary nephritis and sensorineural deafness. This complex has been referred to as Epstein syndrome or Fechtner syndrome when associated with leukocyte cytoplasmic inclusions (Table 1).

MANAGEMENT

Currently there is no specific treatment available for Alport syndrome. Angiotensin antagonists (ACE inhibitors and/or Angiotensin receptor blockers) and cyclosporine are being used currently for delaying the progression of disease.^{9,10} In patients who develop end-stage renal disease, transplantation is the preferred modality for renal replacement therapy. Recurrent disease does not occur

Table 1: Familial glomerular hematurias

	<i>Genetic locus</i>	<i>Protein product</i>	<i>Renal symptoms</i>	<i>ESRD</i>	<i>GBM Ultrastructure</i>	<i>Extrarenal manifestations</i>
<i>Type IV collagen disorders</i>						
<i>Alport syndrome</i>						
X-linked	<i>COL4A5</i>	$\alpha 5(\text{IV})$	Hematuria, proteinuria, hypertension	All males, some females	Thinning (early) lamellation (late)	Deafness, lenticonus, perimacular flecks
Autosomal recessive	<i>COL4A3</i> <i>COL4A4</i> (biallelic)	$\alpha 3(\text{IV})$ $\alpha 4(\text{IV})$	Hematuria, proteinuria, hypertension	All males and females	Thinning (early), lamellation (late)	Deafness, lenticonus, perimacular
Autosomal dominant	<i>COL4A3</i> <i>COL4A4</i> (heterozygous)	$\alpha 3(\text{IV})$ $\alpha 4(\text{IV})$	Hematuria, proteinuria, hypertension	Males and females (late)	Thinning (early), lamellation (late)	Deafness
Thin basement membrane nephropathy	<i>COL4A3</i> <i>COL4A4</i> (heterozygous)	$\alpha 3(\text{IV})$ $\alpha 4(\text{IV})$	Hematuria	Rare	Thinning	Rare
<i>MYH9 disorders</i>						
Epstein syndrome	<i>MYH9</i> (hyterozygous)	NMMHC-11AA ³	Hematuria, proteinuria	Yes	Lamellation	Deafness, large platelets
Fechtner syndrome	<i>MYH9</i> (hyterozygous)	NMMHC-11AA ³	Hematuria, proteinuria	Yes	Lamellation	Deafness, large platelets, May-Hegglin anomaly

in the transplanted graft because the donor kidney has a normal glomerular basement membrane (GBM). However, anti-glomerular basement membrane antibody disease occurs in approximately 3 percent of affected males who receive transplants.

THIN BASEMENT MEMBRANE DISEASE

It is an autosomal dominant condition resulting in familial persistent microscopic hematuria¹¹. There may be episodes of gross hematuria which may be syn infectious. It is usually not associated with proteinuria, hypertension or progression to end stage renal disease but still patients diagnosed to have this condition should be kept under close follow-up. Proteinuria has been found to occur in up to 30 percent of adult patients as compared to a negligible number in pediatric patients.¹² This diagnosis is mostly pathological rather than clinical. Renal biopsy findings are suggestive of diffuse thinning of glomerular basement membrane, with normal staining for type IV collagen. Light microscopy typically shows no abnormalities. Treatment is usually not required as the course of the disease is very benign.

POLYCYSTIC KIDNEY DISEASE

Polycystic kidney disease can present in 2 genetically distinct forms, autosomal dominant polycystic kidney disease (ADPKD) and autosomal recessive polycystic kidney disease (ARPKD).

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney (ADPKD) is the most common inherited kidney disease, having an incidence of 1 in 1000 livebirths. It is associated with mutations in PKD1 (85 percent) and PKD 2 gene encoding polycystin 1 and 2.¹¹ ADPKD has a variable presentation and it varies even within families. A positive family history may be obtained in approximately 60 percent of the patients. The presentation can be:

- Antenatal ultrasound showing large kidneys with or without cysts, occasionally associated with oligohydramnios.
- In children, ADPKD may be detected incidentally or on screening at any age including neonatal age group. Symptoms are rare during childhood. Occasionally they may present with abdominal pain, palpable abdominal mass, gross/microscopic hematuria, urinary tract infection, hypertension or nephrolithiasis.
- Adults may be asymptomatic with cysts being incidentally detected on ultrasound.
- Chronic kidney disease may be seen in 60 to 70 percent patients usually by sixth decade of life.

Table 2: Diagnostic criteria for ADPKD

Positive family history with autosomal dominant pattern

- Ultrasound screening of parents may be positive

Enlarged kidneys with multiple bilateral renal cysts (on ultrasound or CT scan)

- Age 15-39 years: >2 renal cysts (unilateral/bilateral)
- Age 40-59 years: >1 renal cyst in each kidney
- Age >60 years: >3 renal cysts

- *Extra renal manifestations:* Cysts in the liver, pancreas, spleen, ovaries, testis; cerebral aneurysms, mitral valve prolapse and coarctation of aorta.

The condition can be diagnosed with ultrasound showing one or more cysts, although a negative ultrasound does not exclude ADPKD till fourth decade of life. The diagnostic criteria for ADPKD as described by Pei et al¹³ are shown in Table 2.

Family screening can be undertaken for parents of index case, or grandparents if parents are younger than 30 years.¹⁴ If the child is asymptomatic, USG screening should be done every 5 years. The child also needs to be screened for hypertension and proteinuria on an annual basis. There is no specific treatment for ADPKD, but if the child is having hypertension or proteinuria then ACE inhibitors may be used. Reduction of cyst volume by surgical decompression or percutaneous aspiration may be done for painful cysts. Sirolimus or *everolimus* may be tried to retard the cyst growth and delay the onset of renal failure.

Autosomal Recessive Polycystic Kidney Disease

The incidence of autosomal recessive polycystic kidney disease (ARPKD) is 1 in 10,000 to 40,000 livebirths. The underlying genetic defect is in PKHD 1 gene which codes for fibrocystin. The clinical presentation is variable:

- Antenatal ultrasound may show enlarged kidneys with loss of *corticomedullary* differentiation and *oligohydramnios*. Majority of patients with ARPKD present in infancy. They may have Potter's phenotype with large palpable flank masses and pulmonary hypoplasia. They may also have renal insufficiency at birth.¹⁵
- In older children, the presentation may be with hypertension, polyuria, renal dysfunction or recurrent urinary tract infections.
- Chronic kidney disease may also be a presenting feature as it occurs very early during the natural course of the disease.
- The extra renal manifestations of the disease include:
 - Liver involvement is overt in 50 to 60 percent and microscopic abnormality is seen in 100 percent of the patients. Congenital hepatic fibrosis may present with hepatomegaly and portal hypertension. Histopathology shows ductal plate abnormalities.¹⁶

Table 3: Diagnostic criteria for diagnosis of ARPKD

Ultrasound features – enlarged, echogenic kidneys with poor corticomedullary differentiation
One or more of the following:

- Absence of renal cysts in both parents when aged more than 30 years
- Clinical, laboratory or radiographic evidence of hepatic fibrosis
- Hepatic pathology demonstrating characteristic ductal plate abnormality
- Previous affected sibling with pathologically confirmed disease
- Parental consanguinity suggestive of autosomal recessive inheritance

- Choledochal cysts, Caroli's disease.
- Hypersplenism, esophageal varices and cholangitis may complicate liver disease.

The diagnostic criteria for ARPKD as suggested by Zerres et al¹⁷ are shown in Table 3.

Renal histopathology may reveal medullary duct ectasia, tubular atrophy and interstitial fibrosis. There is no specific treatment but vasopressin receptor antagonists, tyrosine kinase inhibitors, rapamycin and *octreotide* hold some promise. Hypertension needs to be controlled if present¹⁸. Yearly ultrasound for hepatic and splenic size is recommended. Endoscopic evaluation of oesophageal varices can be done along with monitoring of the hematological parameters. Chronic kidney disease should be managed conservatively initially and renal replacement therapy is to be considered if required. If antenatal ultrasonography is suggestive of severely affected fetus with early onset oligohydramnios, termination of pregnancy may be considered.

NEPHRONOPHTHISIS—MEDULLARY CYSTIC DISEASE COMPLEX

It consists of a group of inherited disorders with chronic sclerosing tubulointerstitial nephropathy which results in chronic kidney disease.

Nephronophthisis (NPH)

NPH has an autosomal recessive inheritance and it is the most common genetic cause of chronic kidney disease in the first two decades of life. NPH is classified as infantile NPH, juvenile NPH and adolescent NPH depending on the mutation in NPHP 2, 1 and 3 respectively. NPHP gene encodes nephrocystins. Juvenile onset NPH is the most common type.^{19,20}

Clinical Features

- Insidious onset of chronic kidney disease leading to ESRD by 2nd decade of life

- Polyuria, polydipsia, secondary enuresis
- Anemia, rickets
- Renal salt wasting and salt craving
- Hypertension and hematuria are rare presentations
- Extra renal manifestations:
 - Retinitis pigmentosa in Senior Loken syndrome
 - Oculomotor apraxia
 - Visual loss
 - Hepatic fibrosis
 - Hypoplasia of cerebellar vermis in Joubert's syndrome
 - Situs inversus

Ultrasonography reveals small to normal sized kidneys which are echogenic with small cysts in medulla or cortico medullary junction.

Medullary Cystic Kidney Disease

Medullary cystic kidney disease (MCKD) is an autosomal dominant condition resulting from mutations in MCKD 1 and 2 gene and presents in early adulthood (third decade).²¹ It is associated with hyperuricemia and gout, and not associated with any extra renal features or syndromes. Treatment is symptomatic and involves management of chronic kidney disease. Post-transplant—there is no recurrence of the disease in the renal allograft.

CYSTINOSIS

Cystinosis is an autosomal recessive condition characterized by defective lysosomal transport of cystine, leading to increased intralysosomal cysteine accumulation.²² The defective gene is CTNS, which encodes cystinosisin, a lysosomal membrane protein that promotes cystine exit from lysosomes.

Clinical Presentation

- Symptoms usually become prominent in the second half of infancy, with a median age at onset of symptoms being 10 months.²³
- Poor weight gain or weight loss, inadequate feeding, vomiting, constipation, lethargy, weakness, excessive thirst, and polyuria.
- Growth retardation and vitamin D resistant rickets.
- Blond hair which are sparse and thin.
- Hypothyroidism, impaired glucose tolerance, delayed puberty.
- *Eye:* Fundoscopy may reveal a patchy depigmentation of the retina with peripheral clumps of pigment. Cornea, iris and conjunctiva may show deposition of crystals.
- In the absence of cystine-depleting therapy, progressive glomerular damage leads to end-stage renal disease by the end of the first decade, but this can occur as early as 2 to 3 years.²⁴
- *CNS symptoms:* Bradykinesia, tremors, memory loss, dementia, rigidity, weakness, paresthesia, dysarthria, and dysphagia.

Management includes supportive treatment, conservative treatment for chronic kidney disease along with initiation of oral cysteamine therapy. Cysteamine eye drops have also been tried to prevent deposition of cystine crystals in the eyes. Renal transplantation is successful but it doesn't correct the systemic disorder and cystine continues to accumulate in the nonrenal tissues.

NAIL PATELLA SYNDROME

Nail patella syndrome is an autosomal dominant condition resulting from the mutation of LMNX1B gene. The clinical features of this condition include absent or hypoplastic patella with dystrophic nails.²⁵ Pelvis X-ray may reveal iliac horns. Renal involvement may be in the form of proteinuria, hypertension, hematuria, urinary acidification and concentration defect. In this condition, chronic kidney disease may occur in 10 to 20 percent of the cases. Treatment with ACE inhibitors may be initiated to reduce the proteinuria and manage hypertension.

LOWE SYNDROME

Lowe syndrome is better known as oculocerebrorenal syndrome and it has a X-linked recessive inheritance. The gene mutated in this disorder is OCRL1 gene. In this syndrome, there is involvement of eyes, brain and kidneys.²⁶ Renal manifestations include Fanconi syndrome, hypercalciuria, nephrocalcinosis, urolithiasis and end stage renal disease (ESRD). Extrarenal manifestations include glaucoma, cataract, psychomotor retardation and hypotonia.¹¹

Rajeev Kulshreshtha

Inguinoscrotal Swelling

Kapil Vidyarthi

Inguinoscrotal swelling is one of the most common surgical problems encountered in children. Common nonacute surgical problems in the region are:

- Abnormalities of processus vaginalis
- Abnormalities of descent of testis
- Varicocele
- Lymphadenitis
- Saphena varix
- Lymphangiectasia
- Diffuse lipoma of cord
- Benign neoplasms
- Malignant tumors.

ABNORMALITIES OF PROCESSUS VAGINALIS

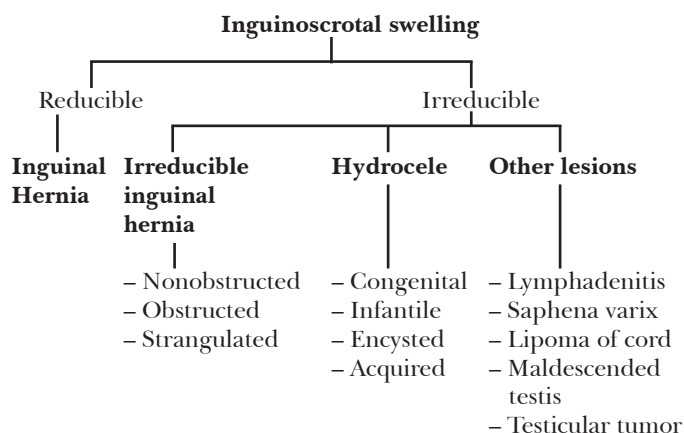

Processus vaginalis is the covering of testis. It normally closes before birth. If it fails to close it gives rise to various abnormalities detailed below (Figs 1A and B). If the communication with the peritoneum is big it gives rise to hernia (Fig. 2) and if the communication is small, it gives rise to *hydrocele* (Figs 3 and 4).

Processus vaginalis is integral part of the process of descent of testis by providing necessary hydraulic force for the descent. It tends to close around birth of the child. However in approximately 20 percent individuals it tends to remain patent throughout life without causing hernia.

A patent processus vaginalis is a potential hernia.¹ However all processus vaginalis are not troublemakers. There are some *factors responsible for herniation* in patent processus vaginalis. These are undescended testis, exstrophy bladder, ascites, ventriculoperitoneal shunt, connective tissue disorders and chronic respiratory diseases. Inguinal hernias and hydrocele are the most common problems associated with patent processus vaginalis.

Approach to an inguinoscrotal swelling can be summarized in Flow chart 1.

Flow chart 1: Inguinoscrotal swelling

INGUINAL HERNIA

About three to five percent of healthy,² full-term babies may be born with an inguinal hernia and one-third of hernias of infancy and childhood appear in the first 6 months of life. In premature infants, the incidence of inguinal hernia is substantially increased, up to 30 percent. In just over 10 percent of cases, there can be a family history of similar problem. Inguinal hernia is associated with a multitude of genetic syndromes.³ Disorders of the microfibril, elastin, collagen, and the glycosaminoglycan component of the extracellular matrix can result in an increase in the likelihood of inguinal hernia. In addition, inguinal hernia may be the presenting feature of disorders of sexual differentiation. Inguinal hernia of unknown etiology also occurs more commonly in several other groups of genetic diseases including chromosomal disorders, microdeletion disorders such as 2q11.2 microdeletion, and in single gene disorders.⁴ However, overall chances of inguinal hernia being a part of genetic disorder is low and does not merit

Figs 1A and B: Processus vaginalis: (A) Open; (B) Closed

Fig. 2: Left inguinal hernia

Fig. 3: Infantile hydrocele

Fig. 4: Encysted hydrocele of cord

genetic work-up. However, connective tissue abnormalities, a part of many genetic disorders, are predisposing factors for PPV culminating into inguinal hernia. Right side hernias are commoner than left. Inguinal hernia is less common in girls.

Clinical Presentation

A reducible swelling in one or both inguinoscrotal regions, is an inguinal hernia unless and until proved otherwise. Diagnosis is obvious and does not require any further investigations. However more often the child is brought with history of such swelling with no apparent abnormality on examination. It may not be possible to make the child strain to elicit impulse, as the child may be too small to comply with the request. Even a bigger child may not understand the importance of the request and may not fall in line. *Ultrasonography* and *computerized tomography (CT) scan* have been ordered with absolutely no additional help. The defect will be revealed only if contents are present at time of examination by whatever means. Moreover, in event of a negative imaging, it becomes difficult for the lay relatives to understand that the problem actually exists.

In such situation, *definite history* by a responsible and intelligent parent can be considered sufficient. A *digital photograph* taken at the time of swelling can be still more helpful.⁵ Gentle rolling of spermatic cord over a bony prominence, like pubic tubercle, usually reveals a feeling of rubbing rubber – *silky glove sign*. The finding is due to thickened spermatic cord as well as hypertrophied cremasteric muscle.⁶ The finding is an irrefutable evidence of a patent processus, most likely a hernia.

Treatment

There is no dispute that the treatment of reducible inguinal hernia is an elective *herniotomy* under general anesthesia. There is plenty of discussion in recent past

about *open versus laparoscopic* herniotomy. At present, there is no definite proved advantage of one over the other. It also depends on surgical acumen of the surgeon. An accomplished laparoscopist will be able to do as good a job as an expert nonlaparoscopic surgeon.

In past, surgeons used to resort to *contralateral exploration* to avoid second surgery. At present, pediatric anesthesia is reasonably safe even in preterms and medically compromised children.⁷ Thus contralateral exploration is not warranted. Contralateral exploration exposes the delicate cord structures to unnecessary handling especially when the sac does not exist. However, it will be prudent on the part of surgeon, to explain to the parents the possibility of contralateral hernia developing at a later date.

The *timing of surgery* is, at presentation. There is no wisdom in waiting and getting the hernia obstructed with its associated complications. There has been discussion on timing of herniotomy in a neonate, specially prematures, in view of reports of postanesthesia apnea in these children.⁸ However, obstruction is more troublesome in these patients and it is advisable to operate them before they are discharged from NICU. By that time comorbid conditions will have been taken care of anyway.

Herniotomy might not be adequate in the presence of connective tissue disorders and some form of posterior wall repair may have to be added to reduce the possibility of a recurrence. There are reports of spontaneous closure of processus vaginalis and cure of inguinal hernia⁹ especially in neonates and prematures. However, one has to be extremely vigilant about obstruction. The author would not like to advocate it especially in our context where availability of surgical expertise is not absolutely guaranteed.

Irreducible hernia: In the absence of signs of obstruction or strangulation, an attempt may be made to reduce the hernia by gentle manipulation, aided by sedation and elevation of foot end of the bed. It will be worthwhile postponing surgery for 48 to 72 hours if satisfactory reduction has been achieved. This reduces the edema and makes surgery safer from patient's point of view. If not reduced, it should be treated as an obstructed hernia.

Obstructed inguinal hernia: In the presence of clinical evidence of intestinal obstruction, emergency surgical intervention is needed. It is still possible to open the sac, reduce the contents and proceed with herniotomy.

Strangulated inguinal hernia: When there are signs of vascular compromise and systemic evidence of toxemia, it is better to undertake a laparotomy and handle the gut from the peritoneal aspect. It may still be possible to do a herniotomy, approaching the internal ring from within.

HYDROCELE

We have a patent processus vaginalis communicating with peritoneum as in an inguinal hernia. However, the

communication is small and intestines do not come out. It is only peritoneal fluid which forms the contents. It is *not possible to reduce* the contents manually because of 'inverted ink bottle effect'. The contents will be *transilluminant*. There is no tenderness or any other sign of inflammation. In a communicating hydrocele, there may not be a swelling when the child wakes from sleep. During sleep, the fluid quietly slips back into the peritoneal cavity. It reappears, when the activity resumes in the form of kicking and playing.

In a noncommunicating and encysted hydrocele, this finding will not be there.

Treatment is herniotomy under general anesthesia. There is no controversy about approach to this. The approach has to be inguinal rather than scrotal. We have to close the internal ring. Eversion of sac is bound to lead to recurrence as the basic problem has not been tackled. However in these cases one can safely wait for spontaneous closure of communication. It is advisable to wait for at least 18 months. At least 75 percent will automatically get cured. Alternative medicine takes credit for these type of cases. It is not uncommon to find a child cured of inguinoscrotal swelling by touching a brinjal, blessed by a babaji, to the swelling and keeping at an unapproachable place. The swelling shrinks with the brinjal. The fact is that it would have shrunk any way with or without treatment. Placebos have also been tried for this. The treatment is sometimes used in an inguinal hernia rather than hydrocele with its own peril.

INGUINAL LYMPHADENITIS

The region richly abounds in lymph nodes and all abnormalities of lymphatic system are bound to reflect in the area. These are nonreducible, lobulated, nontransilluminant and much more firm than other abnormalities in the area. An inflammatory mass will be tender on palpation. An abscess may be fluctuant. The nodes are more often nonspecific and reactive in this area. However, tuberculosis, lymphoma, etc. form important differential diagnosis as lymphadenopathy anywhere else in body. The problem is dealt with in detail in other sections.

TESTICULAR NEOPLASM

Any firm to hard, nontender testicular swelling is highly suspicious and is to be treated as neoplastic unless proved otherwise.

Clinical Presentation

About 85 percent of children with testicular tumors present with *painless scrotal swelling*. There may be a *secondary hydrocele* in 10 to 25 percent cases. At times *scrotal pain* may be a presenting complaint. A *history of trauma* may be present. But more often the incident alerts the child to the

presence of a painless and enlarged testicle rather than causing it.

Physical examination usually reveals a painless scrotal swelling with a firm to hard consistency or associated hydrocele. Some hormonally active tumors may appear in association with *precocious puberty* or *gynecomastia*. The lesion is *nontransilluminant* and is mainly *limited to scrotum*. However, at times, there is growth of tumor along spermatic cord giving rise to an *inguinoscrotal swelling*.

Testicular tumors are reported to be benign in approximately 70 percent cases. Benign teratoma is the most common testicular tumor, followed by Leydig-cell tumor, epidermoid cyst and Sertoli cell tumor. Other benign tumors are cystic dysplasia, and intratesticular focal fibrosis. Malignancy has been reported in approximately 30 percent of cases. Common malignant tumors are yolk-sac tumor, and embryonal carcinoma. Malignant tumors are more often reported in adolescents (77%).¹⁰

Treatment

Orchiectomy has traditionally been the gold standard for testicular tumors in children. Any suspicion of the testicular tumor warrants an inguinal approach to prevent scrotal violation by the tumor. Current trends emphasize that testis-sparing surgery should be performed for benign lesions such as teratoma, Leydig cell tumor, and epidermoid cyst based on frozen biopsy findings. Literature findings and our experience suggest that radical inguinal orchidectomy is the accurate treatment for Stage I malignant germ cell tumors and Group I and IIa paratesticular rhabdomyosarcoma. Retroperitoneal lymph node excision is not of benefit either as a staging or therapeutic procedure in Stage I and Group I and IIa diseases of these tumors.¹¹ Retroperitoneal lymph node excision should be reserved for malignant germ cell tumors patients who have persistent elevation of alpha-fetoprotein after orchiectomy in the presence of normal total body CT scan, and for patients presenting with Stage II and III disease with definitive abnormality on CT scans, and group IIb, Ic, and III paratesticular rhabdomyosarcoma patients with radiologic evidence of retroperitoneal involvement on CT scans. High ligation should be done as a complementary procedure after scrotal orchiectomy to increase the survival rates.

VARICOCELE

A varicocele is mass of enlarged and swollen veins in the testicle that essentially feels like a bag of worms. A varicocele is generally neither harmful nor painful. However, it can cause a discomfort and a dragging sensation in groin. Approximately 15 percent of boys have this condition, which almost always occurs on the left side since left testicular vein drains into renal vein and has no valves. Therefore, the pressure of larger veins is transmitted to

it. A varicocele usually develops at puberty, but can occur earlier. A varicocele developing in a younger child should alert to the possibility of a lesion in its drainage area, e.g. renal tumor. Only occasionally does an adolescent with a varicocele experience any pain or discomfort. Therefore, the condition is usually discovered during a routine physical examinations or incidentally while bathing, when the large veins can be easily seen and felt. Physical examination in standing posture reveals the lesion more often. There may be an impulse on coughing. The swelling may reduce completely on lying down. Horizontal lie of the testis has recently been observed in association with varicoceles in a pediatric population. The condition may revert to normal after surgery for varicocele has been performed. Horizontal lie of the testis in children is a new clinical sign that should alert the examiner to the possibility of an underlying varicocele.¹²

Treatment, if required can be an open or laparoscopic ligation of testicular vein.

Saphena varix is a varicosity of saphenous vein at its drainage into femoral vein. It is not common in children. If present, a cause has to be found out and managed.

UNDESCENDED TESTIS

At times, the testis can be palpated in inguinal region usually in superficial inguinal pouch. If it can be manipulated into the scrotum, it is labeled as retractile testis and needs no further treatment. A true undescended testis cannot be brought to scrotum by manipulation and has to be surgically corrected. A word of caution about imaging studies in this regard. A retractile testis present in canal at time of imaging – ultrasound/ CT/ MRI – will be labeled as undescended testis unless manipulated at time of procedure. Clinical examination is more informative in this regard.

Other benign tumors: Lipoma of cord, lymphangioma of cord and lymphangie, etc. can present as inguinoscrotal swelling. The attachment to cord can be ascertained by fixing the cord, by pulling the testis down and making it

taut. A tumor attached to cord will move along with the cord and vice versa.

Abdominal Trauma

Alpana Prasad

INTRODUCTION

Abdominal trauma is one of the major causes of severe injury in children. It is the most common initially missed fatal injury in childhood.¹ It accounts for approximately 10 percent of deaths from injury in childhood. To minimize the morbidity and mortality associated with these injuries, a high degree of suspicion and an early diagnosis is essential.

Abdominal injury in children is mainly due to blunt trauma, with road-traffic accidents being the reason in majority of cases.² Pedestrian injuries are the second most common cause of abdominal injury in children. The mechanism of injury depends on the chronologic and developmental age of the child and it determines the pattern of other associated injuries. Injury due to fall is more common in toddlers and causes significant associated head and extremity injuries.³ Pedestrian and bicycle injuries are more often seen in school age children and may cause multiple injuries to head, neck, trunk and extremities. Bicycle handlebar injuries in children include traumatic pancreatitis, renal and splenic injury, duodenal hematoma and bowel perforation.⁴ Abdominal injury may be caused by seatbelt which has been incorrectly used or is not suitable for a small child. Penetrating injuries such as gun-shots and stab-wounds are less common and seen in older children and adolescents and account for a disproportionate number of trauma related deaths. Abdominal trauma secondary to abuse is not uncommon particularly in younger children with delayed presentation and relatively more severe injuries.

There is a higher risk of multiple organ injury in a child as the kinetic energy from an external force is absorbed by a body mass that is considerably smaller. Also the relatively large, superficial liver, spleen and the kidneys are not well protected from blunt trauma by the pliable ribs and thin abdominal wall muscles, and organ

injury may occur without fracture of the overlying ribs.³ In children the kidneys retain fetal lobulations which may lead to easier separation and fracture and also the urinary bladder is an intra-abdominal organ and at risk during abdominal trauma.

ASSESSMENT OF A CHILD WITH ABDOMINAL INJURY

Clinical assessment begins with primary survey ABCDE sequence (airway, breathing, circulation, disability, exposure) and resuscitation. Oxygenation and ventilation must be the priority as the main cause of cardiac arrest in children is respiratory arrest. Early signs of bleeding in an injured child are tachycardia and cold peripheries. Blood pressure is not a reliable indicator of circulatory status. An intra-abdominal or pelvic injury must be suspected when the primary survey reveals evidence of bleeding without an obvious injury to account for this. The child is methodically examined for injuries in the secondary survey. A child's stage of development and inability to communicate verbally may delay the examination. Any external evidence of injury on the abdomen is noted. Abdominal distension, tenderness and guarding indicate an intra-abdominal pathology and worsening of these abdominal signs suggest progressive peritonitis from bleeding or intestinal or bladder injury. Physical examination of a child's abdomen in trauma has been generally considered an unreliable and inaccurate indicator of injury and may lead to missed injuries.¹ Hence, these children need to undergo further investigations to identify their injuries.

Laboratory investigations may be relatively normal on admission and to detect an evolving pathology, serial measurements are necessary. Progressive fall in hemoglobin and hematocrit may be an evidence of continuing hemorrhage. Persistent metabolic acidosis may indicate hypovolemia or tissue ischemia as seen in intestinal

injury, while progressively rising serum amylase levels suggest pancreatic duct injury. Other than a urine analysis, routine “trauma panels” are not sensitive or specific for identifying intra-abdominal injury in children.^{5,6} Elevation of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are predictive of internal abdominal injury.⁷

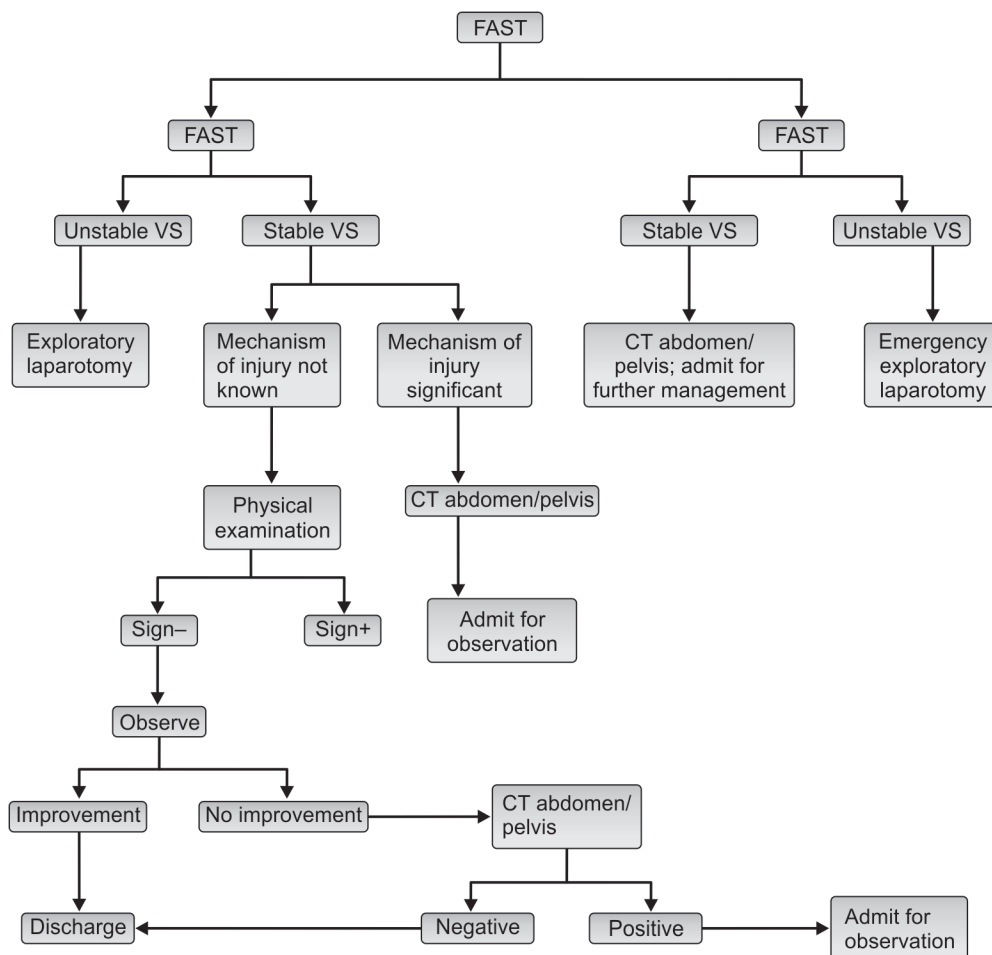

There is an increasing reliance on imaging modalities to identify intra-abdominal injuries since the increasing prevalence of nonoperative management. The modern imaging techniques like ultrasound and CT scan have become sensitive but they have their limitations. The initial emergency X-rays must include an AP view of the abdomen and pelvis to identify pneumoperitoneum, or acute gastric dilatation or any pelvic fracture besides those of the cervical spine and chest.

Focused abdominal sonography for trauma (FAST) is portable, easy, quick and noninvasive modality for initial screening of children with abdominal trauma for

identification of solid organ injury and free intraperitoneal fluid.⁸ The FAST examination in children has a high specificity (95%) but low sensitivity (33%) in identifying intestinal injury, and it does not provide the same information as a CT scan.^{9,10} A positive FAST exam in a hemodynamically unstable child would indicate an urgent laparotomy whereas the same in a stable child should be followed by abdominal CT scan to better define the injury.¹¹ A negative FAST in an unstable patient warrants examination for an extra-abdominal source of bleeding, while in a stable patient it should be followed with observation for any evolving symptoms and follow-up FAST or CT scan according to the clinical condition. Ultrasound should be used in conjunction with physical examination and laboratory investigations to determine the need for further imaging studies (Flow chart 1).

The preferred method for identifying abdominal and retroperitoneal injuries is CT scan with intravenous contrast enhancement. The greatest limitation of abdominal

Flow chart 1: Algorithm for imaging in pediatric abdominal trauma

FAST – Focused abdominal sonography for trauma
VS – Vital sign

CT in trauma is the inability to reliably diagnose bowel injury. The presence of free intraperitoneal fluid in the absence of an injury to solid organs must raise suspicion of intestinal perforation. CT is contraindicated when there is respiratory or hemodynamic instability or if there is an extra-abdominal injury like a head injury requiring immediate intervention.^{12,13}

Diagnostic peritoneal lavage (DPL) may be useful in evaluating the abdomen of an unconscious child who is too unstable to be shifted for CECT abdomen or when imaging facility is not available. Routine use of DPL in children is not recommended because it is painful and hence, will make subsequent clinical assessment difficult and presence of residual lavage fluid will cause confusion in interpretation of follow-up US or CT scan. Intravenous pyelography and angiography are useful in selected situations. Tc-99 radioisotope scanning may be rarely used.

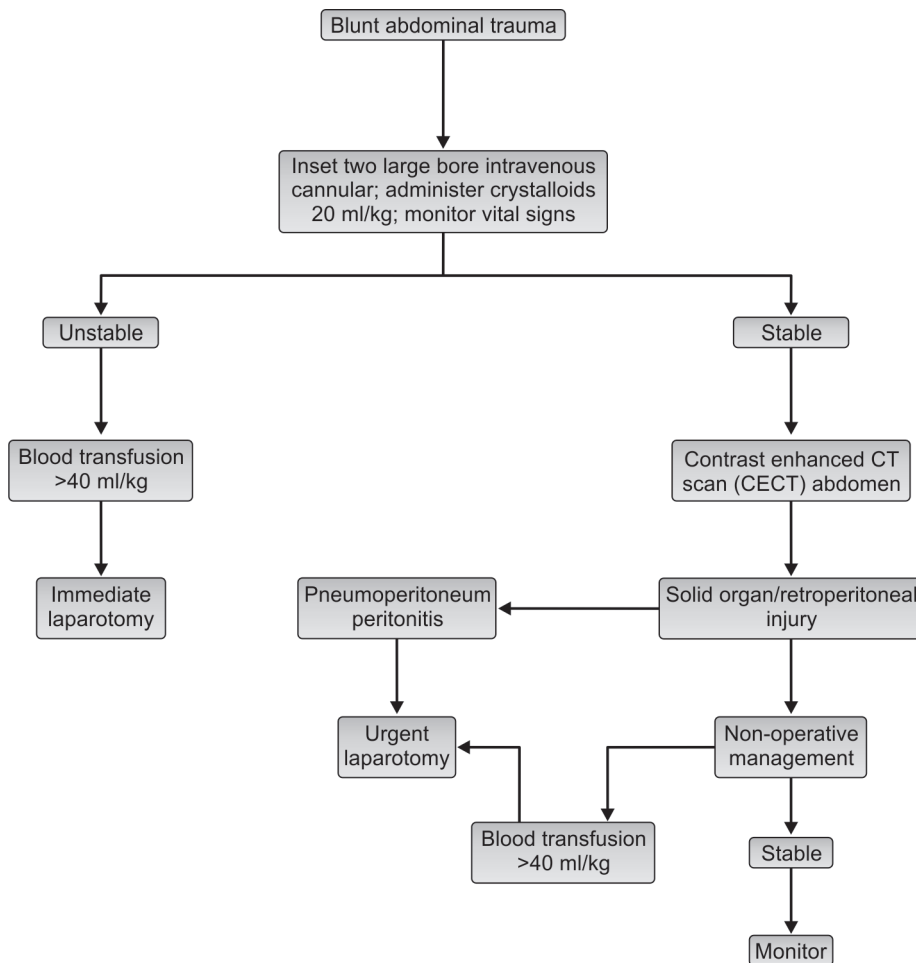

It must be remembered that there are some injuries that can be missed even on a CECT scan and hence, observation at a tertiary trauma center is the only proven modality to decrease the risk of missed abdominal trauma.¹⁴

MANAGEMENT

The general principles of emergency management of a child with abdominal trauma should follow advanced trauma life support (ATLS) and advanced pediatric life support (APLS) guidelines. Vital signs are monitored. For rapid infusion of fluids, two large bore intravenous lines are inserted. A nasogastric tube is inserted to empty the stomach and a urethral catheter is placed to measure urine output accurately. A suprapubic catheter may be required if there is blood at the urethral meatus. Hypovolemic shock is managed by administering initial fluid bolus of crystalloids, normal saline or ringer lactate, and later whole blood or packed cells depending on the rate of hemorrhage and the degree of shock. A child in severe shock would require intubation and mechanical ventilation (Flow chart 2).

Management of abdominal injuries in children has evolved significantly over the last four decades. The observation that most solid organ injuries would “heal themselves” and that operative intervention could interfere with this healing process, provided the basis for the development of

Flow chart 2: Algorithm for management blunt trauma abdomen

the current concept of nonoperative management for most blunt solid organ injuries.^{15,16} In patients with solid organ injury, the risk of hollow viscus injury is three to four percent and increases with the number of injured solid organs. Hence, the child needs to be admitted for repeated clinical assessments, continuous monitoring of vital signs and urine output, serial estimations of hemoglobin, hematocrit and serum amylase levels as indicated. This is the most sensitive method to detect a hollow visceral or mesenteric injury that may require laparotomy.¹⁷

INDICATIONS FOR SURGERY

Continuing hemorrhage requiring transfusion in excess of 40 ml/kg of packed red blood cells remains to be the most common indication for surgical exploration. Laparotomy is also indicated for penetrating injuries and when there is evidence of intestinal, mesenteric or a major pancreatic injury. Bleeding and hollow visceral injury aside, a percentage of conservatively managed patients may ultimately come to some type of intervention for ongoing complications, particularly biliary and urine leaks as well as delayed vascular complications. The majority of these can be managed outside of the acute period and in addition, many interventions will be performed percutaneously and endoscopically, avoiding open exploration.^{18,19} Despite their delayed intervention, the long-term outcome of this group of patients is not compromised, with the benefit that they spared the insults of early surgery.

Role of laparoscopy in pediatric abdominal trauma is yet to be defined. It has been recommended as an alternative to laparotomy in blunt abdominal trauma and also in stable children with penetrating wound of the abdominal wall.²⁰

MANAGEMENT OF SPECIFIC ORGAN INJURIES

Splenic Injury

Spleen is the most commonly injured organ in blunt abdominal trauma in children as it is not well protected by overlying ribs. More than 50 percent of these children have

multiple solid organ injuries mainly to the liver and left kidney and up to 85 percent have extraabdominal injuries. Splenic injury presents clinically with left upper quadrant pain and tenderness and referred pain to the left shoulder. Chest X-ray may show contusion in the lower lobe of left lung, often without overlying rib fracture. In a hemodynamically stable child, an abdominal CECT scan helps in diagnosing and grading the splenic injury (Table 1).²

The immediate consequence of splenic trauma is hemorrhage and in >90 percent cases the bleeding stops spontaneously within hours of injury. Following initial resuscitation, children who remain hemodynamically unstable, requiring blood transfusion >40 ml/kg or are suspected to have another intra-abdominal injury requiring exploration, are an absolute indication for surgery.^{21,22} Spleen should be preserved whenever possible and techniques like partial splenectomy, splenorrhaphy, splenic artery ligation and selective splenic artery embolization have become the mainstay of splenic injury management. Splenic preservation prevents overwhelming postsplenectomy infection (OPSI), which has an incidence of 2 to 11 percent following post-traumatic splenectomy and a mortality rate of up to 50 percent.²³

Nonoperative management involves hospitalisation for bed rest and monitoring until the abdominal signs have resolved. Majority of the hemodynamically stable children with isolated blunt splenic injuries can be treated safely with less than a week hospital stay, followed by three weeks of quiet activity at home and then three months of light activity with avoidance of contact sports, followed by resumption of complete, normal lifestyle. Less than 10 percent of children with isolated splenic injury require a blood transfusion. Delayed complications in these patients are rare. Secondary acute hemorrhage or rupture of a subcapsular hematoma may necessitate blood transfusion and splenectomy. Fatal delayed hemorrhage is very rare but a devastating complication and hence, residual hematoma needs to be followed up closely. Splenic abscess, if detected, can be drained percutaneously. Non-operative management of pediatric splenic injuries leads to complete recovery in 90 to 98 percent of patients.

Table 1: Grading of splenic injuries

Grade 1	Subcapsular hematoma <10% of surface area or capsular tear <1 cm in depth
Grade 2	Subcapsular hematoma of 10-50% of surface area, intraparenchymal hematoma of <5 cm in diameter or laceration of 1-3 cm in depth and not involving trabecular vessels
Grade 3	Subcapsular hematoma >50% of surface area or expanding and ruptured subcapsular or parenchymal hematoma, intraparenchymal hematoma of >5 cm or expanding, or laceration >3 cm in depth or involving trabecular vessels
Grade 4	Laceration involving segmental or hilar vessels with devascularization of >25% of the spleen
Grade 5	Shattered spleen or hilar vascular injury

Hepatic Injury

Liver is the second most common intra-abdominal organ to be injured following blunt trauma in children as it is relatively large and unprotected. It should be suspected in any child with significant mechanism of injury, with right upper abdominal pain or tenderness or contusion or right rib fractures. Injury to the porta hepatis may be associated with damage to the duodenum and pancreas. Gallbladder and extrahepatic bile duct injuries are rare and may present with a biloma or biliary fistula.

In hemodynamically stable patients, CECT abdomen is done for grading the extent and pattern of liver injury.²⁴ In unstable patients, diagnosis should be made at laparotomy. Laboratory finding predictive of hepatic injury is AST >400 IU/L or ALT >250 IU/L. It has been shown that increased ALT levels of more than 131 IU/L and the presence of abdominal trauma were indicative of intra-abdominal injury with 100 percent sensitivity.²⁵

Management depends on the hemodynamic stability of the child and not on anatomical grade of the injury. Stable patients are managed nonoperatively by serial abdominal examination and serial hematocrit and liver enzyme estimation. If despite fluid resuscitation and blood transfusion, a child is unstable, then an exploratory laparotomy is indicated (Table 2).

Majority of children (85-90%) with blunt hepatic trauma have relatively low-grade (grade 1-3) injuries that can be managed nonoperatively and of these only 2 to 10 percent required a blood transfusion. Angiographic embolization is gaining acceptance in the management of higher grade hepatic injuries.^{25,26}

The risk of complications following nonoperative management is approximately 10 percent, which includes delayed hemorrhage, abscess formation and bilioma. In symptomatic patients, follow-up imaging with USG or CT scan is recommended to identify residual hematoma or other fluid collections. Intra-abdominal bleeding is the

major cause of death from liver injury. Hepatic injuries have a higher mortality risk (2.5%) than splenic injuries (0.7%), and hepatosplenic injuries have the highest risk of mortality (8.6%).²⁴

Pancreatic Injury

As compared to other solid organ injuries, pancreatic injury is relatively uncommon, occurring in 3 to 12 percent of children with abdominal trauma. It is almost always due to blunt trauma causing compression of the pancreas against the lumbar vertebral column. Fall on to the handlebar of a bicycle or a deliberate blow or kick are a common mechanism of pancreatic injury. Injury to head of pancreas may be associated with duodenal and bile duct injury, while injury to tail of pancreas may be associated with splenic injury. Due to the retroperitoneal location of the pancreas, its injury is difficult to diagnose initially as the clinical signs and laboratory markers may be subtle and require time to evolve. A progressive rise in serum amylase levels during the first 24 to 48 hours strongly suggests major pancreatic duct injury, however, measurement of serum or urinary lipase level is more specific for pancreatic injury. Abdominal CECT scan is the preferred imaging modality but it tends to underestimate the severity of pancreatic injury and has a widely variable sensitivity ranging from 28 to 85 percent. Pancreatic duct injury is best visualized by endoscopic retrograde cholangiopancreatography (ERCP) or magnetic resonance cholangiopancreatography (MRCP).²⁷ With ERCP there is a risk of pancreatitis or perforation, whereas MRCP is safer, sensitive and noninvasive (Table 3).

Pancreatic injuries without ductal disruption can be safely managed nonoperatively with bowel rest and intravenous feeding and result in low morbidity.²⁷ However, compared to other solid organ injuries, pancreatic injury is most likely to fail nonoperative management.²⁸ Urgent surgery is preferred when the main pancreatic duct has

Table 2: Grading of liver injuries

Grade 1	Subcapsular hematoma <10% surface area, capsular tear, parenchymal laceration <1 cm deep, isolated periportal blood tracking
Grade 2	Subcapsular hematoma 10-50% surface area, intraparenchymal hematoma 1-3 cm thick, parenchymal laceration 1-3 cm deep and <10 cm in length
Grade 3	Subcapsular hematoma >50% surface area or expanding, ruptured, intraparenchymal hematoma >3 cm thick or expanding, parenchymal laceration >3 cm deep
Grade 4	Subcapsular/parenchymal hematoma >10 cm thick, Parenchymal disruption involving 25-75% of hepatic lobe (lobar destruction or devascularization)
Grade 5	Parenchymal disruption involving >75% of hepatic lobe (global destruction or devascularization of liver), juxtahepatic venous injury
Grade 6	Hepatic avulsion

Table 3: Grading of pancreatic injuries

Grade 1	Contusion or hematoma
Grade 2	Capsular or parenchymal disruption without major ductal injury
Grade 3a	Capsular or parenchymal disruption with ductal involvement distal to the superior mesenteric vessels; intact duodenum
Grade 3b	Capsular or parenchymal disruption with ductal involvement to the right of the superior mesenteric vessels; intact duodenum
Grade 4	Combined extensive pancreatic and duodenal crush injury

Table 4: Grading of renal injuries

Grade 1	Contusion, subcapsular hematoma nonexpanding, no laceration
Grade 2	Non-expanding perirenal hematoma, parenchymal laceration <1 cm deep, no urinary extravasation
Grade 3	1 cm deep parenchymal laceration without urinary extravasation
Grade 4	Parenchymal laceration extending through renal cortex, medulla and collecting system, main renal artery or vein injury with contained hemorrhage
Grade 5	Complete shattered kidney, avulsion of renal hilum

been transected with or without associated duodenal injury. Complications of pancreatic injury are pseudocyst formation, pancreatic abscess, fistula, duct stricture and chronic pancreatitis. To monitor the resolution of pancreatic injury and to detect pseudocyst formation, these patients need to be followed with serial serum amylase/lipase estimation and USG or CT scan. More than 50 percent of pseudocysts will resolve with nonoperative management and the remaining may be treated by ultrasound guided percutaneous drainage or endoscopic or open cystogastrostomy. A persistent pancreatic fistula may require excision and a duct stricture is usually treated by endoscopic dilatation and stenting.

Gastrointestinal Tract Injuries

Gastrointestinal tract injuries occur less frequently in children (1-5%) than solid organ injuries, and their clinical presentation is more subtle. Localized blunt force such as a seat belt, cycle handlebar, road traffic accident, or deliberate blow or kick is a common mechanism of intestinal injury. It should be suspected in a child with trauma presenting with abdominal pain and tenderness and on the initial examination there is peritonitis or hemodynamic instability due to mesenteric bleeding. The most important and sensitive method for diagnosing intestinal or mesenteric injury is by serial abdominal examination. Imaging modalities like FAST scans are less sensitive for intestinal injuries and abdominal CT scan with intravenous contrast is preferred.¹⁰ Specific CT scan findings suggestive of intestinal injury are the presence of extraluminal air, extraluminal contrast material, or a moderate-to- large amount

of free fluid without evidence of solid organ injury, and these are indications for surgical exploration.

Intestinal contusion or intramural hematoma may cause temporary intestinal obstruction but usually heal without complication. A hemodynamically stable child with no clear clinical or radiographic evidence of intestinal injury serial monitoring is required. Any child with initial or evolving peritonitis or intestinal injury on imaging should undergo an exploratory laparotomy.

Renal Injuries

Kidney is susceptible to injury in children because of the compliance of the overlying ribs and the paucity of perinephric fat to absorb the energy of an impact. Renal injury should be suspected in any child with significant trauma presenting with abdominal or flank pain, tenderness, ecchymosis or posterior rib fractures.²⁹ Injury to kidneys range from contusion to parenchymal laceration with fragmentation (Table 4). Hematuria is strongly suggestive of renal injury but the degree of hematuria does not correlate with the severity of renal injury (Table 4).

Hemodynamically stable children with gross hematuria should undergo abdominal CT scan with IV contrast to diagnose and grade renal injury. In unstable patients, diagnosis is usually made at laparotomy. The standard practice is renal preservation.³⁰ Nonoperative management is successful in most contusions or parenchymal lacerations with or without urinary extravasation. Perinephric hematoma or urinoma should be monitored by an USG scan. In the presence of a major hemorrhage, ongoing significant hematuria or an expanding flank mass,

angiography with selective embolization is the preferred treatment modality. Complications that may develop following nonoperative management are abscess formation, renal cyst, dystrophic calcification or urethral obstruction. Hypotension is a possible late complication after renal injury and long-term follow-up is advised.

CONCLUSION

Pediatric abdominal trauma management has evolved significantly in the last two decades.^{15,16} Recent advances in the diagnosis and treatment of abdominal injury in children has been contributed by radiologists (improved imaging) and pediatric surgeons (minimal access surgery), which has made pediatric trauma care increasingly non-operative.^{17,18} Nonetheless, in the multidisciplinary care of a critically injured child, the pediatric surgeon should remain in charge as the decision not to operate is always a surgical decision.

Common Pediatric Surgical Emergencies

Kapil Vidyarthi

Mainly consists of Acute abdomen, Acute Scrotum, Respiratory Distress and Trauma. Each one of these problems will be dealt with in details, concentrating mainly on current perspective and controversies.

ACUTE ABDOMEN

It generally refers to acute pain in abdomen. However, vomiting bilious or nonbilious is also usually associated. Systemic manifestations in the form of fever, dehydration or toxemia may also be associated.

The clinical presentation of patients with an acute abdomen is often nonspecific. Both surgical and nonsurgical diseases may present with a similar clinical history and symptoms. Findings may be normal in patients who need emergency surgery (such as appendicitis) and may be abnormal in patients without a surgical disease (like salpingitis).

Laboratory findings (leucocyte count, erythrocyte sedimentation rate, CRP) are equally nonconclusive.

RADIOLOGY

A plain abdominal film has a limited value in the evaluation of abdominal pain. A normal film does not exclude an ileus or other pathology and may falsely reassure the clinician. An ileus (Fig. 1) may not be appreciated on a plain abdominal film if bowel loops are filled with fluid only without intraluminal air. Alternatively if a plain abdominal film does indicate an ileus than sonography or CT are usually needed to identify its cause. Thus, a plain abdominal film is seldom useful, with the exception of detection of kidney stones or a pneumoperitoneum (Fig. 2).

Common causes of acute abdomen are:¹

- | | |
|------------------------------------|------------------------------|
| • Trauma | Appendicitis |
| • Intussusception | Meckel's Diverticulitis |
| • Malrotation with midgut volvulus | Incarcerated inguinal hernia |

- | | |
|---|---------------------------|
| • Peritonitis with or without perforation | Necrotizing enterocolitis |
| • Adhesions with intestinal obstruction | Ruptured ovarian cyst |

Other less common causes are:

- | | |
|-------------------------------|----------------------------|
| • Constipation | Gastrointestinal infection |
| • Other infections | Viral illnesses |
| • Pelvic inflammatory disease | Mesenteric lymphadenitis |
| • Foreign body ingestion | Intestinal colic |

Fig. 1: Small Bowel Obstruction

Fig. 2: Massive Pneumoperitoneum

ACUTE APPENDICITIS

The condition may not be as sinister as it used to be in past, because of availability of modern antibiotics. However, considering morbidity (if not mortality) associated with it, the condition needs a due consideration.

Clinical Presentation

The classic triad of symptomatology consists of pain in periumbilical region shifting to RIF (Kocher's Sign), vomiting – initially ingested food and later bilious, and rebound tenderness in right iliac fossa (Blumberg sign). Low grade fever and leucocytosis are additional features.

Other clinical signs are²—*Rovsing's sign*—pain in right iliac fossa while palpating on Left side of abdomen.

Psoas sign or “*Obraztsova's sign*”: Right lower quadrant pain produced with either the passive extension of the patient's right hip (patient lying on left side, with knee in flexion) or by the patient's active flexion of the right hip while supine.

Obturator sign: Flexing and internal rotation of the hip causes pain in the hypogastrium.

Dunphy's sign: Increased pain in the right lower quadrant with coughing.

Sitkovskiy (Rosenstein)'s sign: Increased pain in the right iliac region as patient lies on his/her left side.

Bartomier-Michelson's sign: Increased pain on palpation at the right iliac region as patient lies on his/her left side compared to when patient was on supine position.

Aure-Rozanova's sign: Increased pain on palpation with finger in right Petit triangle (can be a positive Shchetkin-Bloomberg's sign) - typical in retrocecal position of the appendix.

Investigations

Sonography has the advantage of close patient contact, enabling assessment of the spot of maximum tenderness and the severity of illness without exposing the child to radiation. However, In general the diagnostic accuracy of CT is higher than sonography. In patients with inconclusive US results, CT can serve as an adjunct to sonography, and *vice versa*.

A number of clinical and laboratory based scoring systems have been devised to assist diagnosis -

Alvarado score:³ It is most widely used.

Migratory right iliac fossa pain	1Pt.
RIF Tenderness	2Pts.
Anorexia	1 Pt.
Rebound Tenderness	2 Pts.
Nausea and vomiting	1Pt.
Fever	1 Pt.
Leucocytosis	2 Pts.
Segmented Neutrophils	1 Pt.

A score below 5 is strongly against a diagnosis of appendicitis, while a score of 7 or more is strongly predictive of acute appendicitis. In patients with an equivocal score of 5 to 6, CT scan is used to further reduce the rate of negative appendectomy.

Tzanakis Scoring:⁴

Right lower abdominal tenderness	4 Points
Rebound tenderness	3 Points
Leucocytosis >12,000	2 Points
Positive ultrasound scan	6 Points

A score 8 or more points - >96 percent chance of appendicitis.

At *sonography* and *CT* the appendix is seen as a blind-ending nonperistaltic tubular structure arising from the base of the cecum. *The outer-to-outer diameter of the appendix is the most important imaging criterion*. Although an overlap of appendiceal diameters in normal and inflamed appendices can incidentally be found, a threshold value of 6 to 7 mm is generally used. *A normal appendix has a maximum diameter of 6 mm, is surrounded by homogeneous noninflamed fat, is compressible and often contains intraluminal gas.*

An inflamed appendix has a diameter larger than 6 mm, and is usually surrounded by inflamed fat. The presence of a fecolith or hypervascularity on Doppler, strongly supports inflammation.

CT depicts an inflamed appendix as a fluid-filled blind-ending tubular structure surrounded by fat-stranding. In patients who lack intra-abdominal fat the use of IV contrast can be helpful in depicting the inflamed appendix.

Matrix metalloproteinase (MMP) levels can be used as biomarkers of increased risk of appendiceal rupture among patients with *acute appendicitis* according to a cohort study. MMP-1 was higher in gangrenous ($p<0.05$) and perforated appendicitis ($p<0.01$) compared with controls. MMP-9 was most abundantly expressed in inflamed appendix and reached a tenfold higher expression in all groups with appendicitis compared with controls ($p<0.001$).

Treatment of appendicitis remains surgical excision of inflamed appendix – open or laparoscopic (Figs 3 and 4). The debate is on which of the procedure to resort to. If necessary expertise and equipment are available, *laparoscopy* does have some advantages. The morbidity is much less and we have the advantage of scanning rest of the peritoneal cavity for complications as well as other defects.

Nonoperative outcome: If surgical excision is not resorted to, an attempt is made by the peritoneum to localize the infection with the help of omentum, adjoining bowel loops and exudates. The inflamed organ is encased with the structures and a lump is formed. The lump can be taken care of at a later date – about 6 wks., either laparoscopically or by open surgery.

However, the favorable outcome may not be there in all cases. This is especially, seen in smaller children where omentum is not developed properly. Possible *complications* are—Perforation, gangrene, generalized peritonitis, or septicemia. The intestinal adhesions may lead to intestinal obstruction. Complications can also be handled laparoscopically or by open surgery depending on the expertise of the surgeon.

MECKEL'S DIVERTICULUM

It is a vitellointestinal duct remnant, present in approx. 2 percent of the population and may become symptomatic

at any age. It may remain asymptomatic throughout life. Of the symptomatic patients,⁵ 42 percent present with bowel obstruction, 38 percent have rectal bleeding, 14 percent diverticulitis, and 6 percent umbilical pathology. It is most common differential diagnosis for acute appendicitis. Classical teaching is that if abdomen is opened with a diagnosis of appendicitis and appendix is found normal, look for Meckel's diverticulitis (Fig. 5).

It may also present as

Intestinal Obstruction (42%): Volvulus and intussusception (Fig. 6) are the most common causes of obstruction.

Fig. 4: Open appendectomy (For color version see plate 14)

Fig. 5: Meckel's diverticulum (For color version see plate 15)

Fig. 3: Laparoscopic appendectomy (For color version see plate 14)

Fig. 6: Lead point for intussusception
(For color version see plate 15)

Predisposing factors for bowel obstruction are fibrous bands to umbilicus or mesentery. There are no specific signs and symptoms except small bowel obstruction and diagnosis is made at surgery. Release of band may relieve obstruction. However, if there is vascular compromise resection of devitalized bowel and anastomosis of healthy gut may have to be resorted to. Similarly, if the organ forms the lead point to an intussusception, the aberration has to be corrected and the devitalized bowel is resected. Meckle's diverticulum is excised along with a margin of healthy bowel either by wedge resection or end to end anastomosis.

Hematochezia (38%): Severe painless rectal bleeding may occur. The blood is often altered (maroon colored). However, when bleeding is massive, fresh blood may appear at rectum. A nuclear medicine Meckel scan is positive in 85 percent,⁶ depending on presence or absence of ectopic gastric mucosa. Colonoscopy and gastroscopy rule out other causes of bleeding. In the symptomatic group, ectopic mucosa is present in 61 percent of the resected specimens. Gastric 88 percent, pancreatic 7 percent, and gastric with pancreatic 3 percent were the most common ectopic tissue. The surgical dilemma is whether to remove an asymptomatic diverticulum found incidentally at surgery.⁷

INTUSSUSCEPTION

Intussusception is defined as the telescoping or invagination of a proximal portion of intestine (intussusceptum)

into a more distal portion (intussusciens) is one of the most common causes of bowel obstruction in infants and toddlers. The incidence of intussusception is 1.5 to 4 cases per 1000 live births, with a male-to-female ratio of 3:2. The greatest incidence of idiopathic intussusception is in infants aged 9 to 24 months. A seasonal incidence has been described, with peaks in the spring, summer, and the middle of winter. These periods correspond to peaks in the occurrence of seasonal gastroenteritis and upper respiratory tract infections.

Etiology: Intussusception is ileocolic (see the first image below) in 80 percent of cases but may also be ileoileal, colocolic, or ileoileocolic. Most infants and toddlers (95%) with the condition do not have an identifiable specific lead point. In these idiopathic cases, careful examination may reveal hypertrophied mural lymphoid tissues (Peyer patches), which are due to adenovirus or rotavirus infection. A specific lead point that draws the proximal intestine and its mesentery inward and propagates it distally through peristalsis is identified in only 5 percent of cases and is most commonly found in cases of ileoileal intussusception. Specific lead points are more commonly found in children older than 3 years. Meckel diverticulum is the most common lead point,⁸ followed by polyps, such as with Peutz-Jeghers syndrome, and intestinal duplications. Other lead points described include lymphomas, lymphangiectasias, submucosal hemorrhage with Henoch-Schönlein purpura, trichobezoars with Rapunzel syndrome, caseating granulomas due to abdominal tuberculosis, hemangiomas, and lymphosarcomas.

Children with cystic fibrosis (CF) may present with intussusception due to inspissated meconium in the terminal ileum.

Postoperative jejunoileal or ileoileal intussusception, which has no specific lead point in most cases, accounts for approximately 1 percent of intussusceptions in children of all ages. When a lead point is present with postoperative intussusceptions,⁹ several cases have been reported after appendectomy with stump inversion.⁸ Other rare reported types of intussusception include retrograde jejunojejunal intussusception following duodenal atresia repair and an ileoileal type resulting from blunt abdominal trauma. Although the vast majority of intussusception cases are idiopathic, a familial anatomical tendency that may predispose to the condition in the face of viral infection has also been reported.

Clinical Presentation: Most infants with intussusception have a history of intermittent severe cramping or colicky abdominal pain, occurring every 5 to 30 minutes. During these attacks, the infant screams and flexes at the waist, draws the legs up to the abdomen, and may appear pale. These episodes may last for only a few seconds and are separated by periods of calm normal appearance and activity. However, some infants become quite lethargic

and somnolent between attacks. Early on, the infant may vomit undigested food. As attacks continue, emesis may turn bilious. Stools that appear normal in character early in the course of the illness eventually become dark red and mucoid (resembling currant jelly) - a sign of intestinal ischemia and mucosal sloughing.

Initial inspection may reveal a robust infant who appears healthy. Between attacks, the infant may appear somnolent or quite normal, and findings on examination of the abdomen may be unremarkable. During an attack or spasm, the infant suddenly appears startled or anxious and begins to scream. Upon initial inspection, the abdomen may appear scaphoid; during paroxysms, it may be rigid; and later in the course of the illness, it may become distended with signs of peritonitis. Careful palpation after an attack has subsided may reveal an ill-defined or sausage-shaped mass.

With early ileocolic intussusception, the mass is typically found in the right upper quadrant or abdomen. The right lower quadrant may seem empty upon examination - *Dance sign*. This mass may be difficult to locate in inconsolable infants because of abdominal rigidity from muscle straining. If episodes of cramping are witnessed, the careful examiner may auscultate peristaltic rushes in the area of the intussusception.

The rectal examination should commence with inspection of fecal material in the diaper. Normal-appearing stool should be tested for occult blood. The presence of mucoid or frankly bloody stool supports the diagnosis. Rarely, inspection of the anus reveals the prolapsed tip of the intussusception. A digital rectal examination should be performed routinely, looking for blood or a mass higher in the anal canal.

The 3 strongest clinical predictors for high-risk are: male older than age 5 months and a report of lethargy. If a patient is older than 5 months, then he or she may be considered low-risk if the abdominal radiograph is negative and there is diarrhea with no bilious emesis.

MANAGEMENT

Stable patients in whom the index of suspicion for intussusception is high but who do not have evidence of ischemic bowel, perforation, or sepsis may undergo immediate contrast enema for diagnosis and treatment of suspected intussusception.

Immediate surgery is indicated in unstable patients, in patients who have peritonitis, and in patients with bowel perforation during attempted enema reduction. Elevated temperature and WBC counts have also served as relative indicators for surgery. Patients requiring surgery must be aggressively resuscitated with fluids, and care must be taken to preserve body temperature preoperatively, intraoperatively, and postoperatively.

Plain Radiography

Early in the course of the illness, findings on plain radiographic examination of the abdomen (supine and upright) may be unremarkable. Findings suggestive of intussusception include dilated loops of small bowel with or without air-fluid levels, an airless or opacified right lower quadrant (see the image below), or both. Occasionally, the intussusceptum is apparent on plain abdominal radiography. In order to increase the diagnostic accuracy, a left-side down decubitus radiographic view of the abdomen can be helpful.

Ultrasonography

The utility of ultrasonography in the diagnosis of intussusception has been verified by a number of authors, with a sensitivity and specificity of 100 percent. Characteristic ultrasonographic findings include a *target sign* visible on transverse section and a *pseudo-kidney* sign viewed on longitudinal section. Ultrasonography has also been studied as a tool to help differentiate the types of intussusception. A transient small bowel intussusception is most likely located in the right lower quadrant or periumbilical region, has a smaller anteroposterior diameter (1.38 cm vs 2.53 cm), has a thinner outer rim (0.26 cm vs 0.53 cm), and is absent of lymph nodes, in contrast to ileocolic intussusception. With small bowel intussusception, the length may be helpful in determining the necessity of surgery. An intussusception length of more than 3.5 cm independently predicts the likelihood of surgery being performed, with a sensitivity of 93 percent and specificity of 100 percent.

*Diagnostic and therapeutic enema:*¹⁰ Once the diagnosis of intussusception is entertained, surgical personnel should be notified and an intravenous line and nasogastric tube placed. The surgeon is preferably present in the radiology suite at the time of contrast enema examination. The diagnostic enema is therapeutic in 80 to 90 percent of patients. Thus, treatment is usually concluded in the radiology suite, and these patients are observed until they can tolerate an oral diet. A successful therapeutic reduction must demonstrate free flow of contrast (air or barium series) proximal to the ileocecal valve. Historically, patients in whom enema reduction was unsuccessful were taken immediately to the operating room for laparotomy and manual reduction. However, in patients who are clinically stable, second and third attempts at pneumatic or hydrostatic reduction have proven effective.

Either Barium or Air can be used for contrast enema. Perforation is a risk with either barium or air but poses less of a problem with air; as the combination of barium and feces may result in severe peritonitis with wide peritoneal soilage.

In preparation for contrast study, patients should have intravenous access. A lubricated straight catheter is placed into the rectum and secured by taping the buttocks

together tightly. While many radiologists prefer a balloon-tipped catheter, laceration or perforation of the rectum is a risk with balloon inflation.

A manometer and blood pressure cuff are connected to the catheter, and air is insufflated slowly to a pressure of 70 to 80 mm Hg (maximum 120 mm Hg) and followed fluoroscopically as it percolates proximally through the colon. The column of air stops at the intussusception, and a plain radiograph is taken. If no intussusception exists or if the reduction is successful, air is observed to rapidly pass into the small bowel. Another radiograph is taken at this point, and the air is allowed to escape prior to removal of the catheter. At the completion of the procedure, post-reduction radiography (in supine and decubitus/ upright views) should be used to confirm the absence of free air. Difficult reductions may require several attempts. The use of glucagon (0.5 mg/kg) for facilitating relaxation of the bowel has yielded mixed results and is not routinely used. Success rates of 80 to 90 percent for pneumatic reduction have been reported. In the stable patient, suggestion of a recurrence following enema reduction necessitates a repeat enema examination. Ultrasonographically guided hydrostatic reduction for childhood ileocolic intussusception is preferred because it is safe, accurate, has a higher success rate, and can avoid radiation exposure risk.

Preoperative Management: Expedient diagnosis and management is essential to successful outcomes in infants with intussusception. Once the diagnosis of intussusception is entertained, surgical personnel should be notified, an intravenous line inserted, and intravenous hydration started. A nasogastric tube should be inserted and placed to suction. If the patient is markedly distended or has a dilated loop of bowel, an abdominal radiograph should be obtained. Antibiotics should be administered based on clinical suspicion of peritonitis or infection (sepsis) or in patients with a markedly elevated WBC count.

If the intussusception can be reduced with an enema (Fig. 7), the hospital stay typically lasts 3 days.

Preoperative Details: Preoperatively, intravenous crystalloid resuscitation is begun. Broad-spectrum intravenous antibiotics are administered.

Intraoperative Details (Fig. 8)

The abdomen and bowel are typically explored through a right upper quadrant transverse incision. After inspection for signs of perforation, the intussusception is identified and delivered into the wound. First, an attempt is made at manual reduction by retrograde milking of the intussusceptum. Although gentle pulling may aid in reduction, avoid vigorous pulling apart of the intussuscepted segment of bowel.

If manual reduction is unsuccessful, if a mass or pathologic lead point is present, or if perforation has occurred, segmental bowel resection is necessary. After resection, a

Fig. 7: Barium enema reduction

Fig. 8: Intussusception (For color version see plate 15)

primary anastomosis may be performed. Often, after successful manual reduction, the involved segment of bowel appears edematous, hyperemic, or ischemic. These findings do not necessarily mandate resection. Laparoscopy in the management of intussusception was initially limited to a diagnostic role. It was used to confirm unreduced bowel following an enema with prompt conversion to an open procedure. The laparoscope allowed the surgeons to avoid unnecessary open procedures in cases of spontaneous reduction following enema and enhanced the efficacy of hydrostatic or pneumatic reductions, reducing the need for an open procedure in approximately 30

percent of cases. Continued experience with laparoscopy and improved technology has led some centers to successfully utilize the technique for therapeutic reduction in confirmed cases of pediatric intussusception.
